I consider that the treatment of an acute lymphangitis is not complete without it. In most instances no incision is ever required, but in an infection starting as the lymphatic type we may have secondary involvement with suppuration of the cellular spaces and tendon sheaths of the hand, when active surgical interference will be called for.

#### *Treatment of Suppurative Cellulitis.*

Early incision with free drainage is always indicated. In the finger pulp two lateral incisions will completely relieve tension, and, if made in time, will save the phalanx from necrosis. For deep suppuration in the palm an incision is made in a cleft between two fingers and a sinus forceps thrust in along a lumbrical canal. If this gives inadequate drainage the web of the finger may be split up into the palm. For suppuration in the thenar space through-and-through drainage of the first interosseous space is essential. Incisions on the dorsum of the hand are very seldom required, for the swelling of the dorsum rapidly subsides when the palmar collection is drained.

#### *Treatment of Nail-fold Infection.*

In the severe cases it may be necessary to throw up the nail-fold by a lateral incision at either side and remove part of the nail. As a rule, however, the pus will already have made its way out under the fold. The essential for rapid healing in such cases is to pack in strands of gauze between the nail and the fold by means of the blunt end of a straight sewing needle. This method, which I learned from Mr. J. W. Dowden, is one of the most useful and successful devices of minor surgery.

#### *Treatment of Infective Teno-synovitis.*

Free incision with adequate drainage is necessary at the earliest moment possible. For this, as for the operative treatment of all extensive hand infections, a general anaesthetic should be administered; otherwise inadequate drainage is all too likely. A tourniquet in the form of an Esmarch's bandage to the upper arm is advisable, for not only does the surgeon obtain a clear view of the infected region and its extent with a minimum of haemorrhage, but by leaving on a few turns of the bandage at the conclusion of the operation a suitable degree of passive congestion may be maintained and dangerous toxic absorption diminished.

The opening of infected tendon sheaths should err on the side of completeness, and no thought of subsequent scars should hamper one in providing the freest drainage. If necessary the anterior carpal ligament may be split in order to ensure no retention above it owing to adhesions. If the suppuration has extended into the forearm a lateral incision is made on either side, just in front of the bones, and a forceps thrust through, giving free exit to pus burrowing upwards under the anterior group of forearm muscles. It is a good rule to make all incisions sufficiently free to render the use of drainage tubes unnecessary. The less in the shape of foreign bodies introduced into the wounds the less will be the subsequent fibrosis.

#### *AFTER-TREATMENT.*

Moist dressings and hot saline baths for the first few days should be the rule; they should be stopped, however, as soon as the acute inflammation has subsided, otherwise the tissues become soft and sodden, and resolution is delayed. In the case of cellulitis, rest should be instituted until the infection shows patent signs of becoming localized. Thereafter the sooner movement is encouraged and persevered in the better. In tendon-sheath infections the earlier the movement the fuller will be the ultimate function. With free incisions, passive and active movements facilitate drainage, increase the blood supply, and minimize adhesions. As the inflammation subsides systematic exercises should be carried out every day, and the patient encouraged to strive after a daily advance in the range of movement. To leave restoration of function until the wounds have practically healed is to delay and to compromise the ultimate utility of the hand.

#### *COMPLICATIONS.*

When sloughing of the tendons in one finger has occurred the treatment to be adopted will depend on whether the patient is a manual labourer or no. If the former, then amputation of the finger should be resorted to. To save the finger is only to lose time, as a stiff finger is always in the way. There is, however, a time to amputate and a time to wait. An amputation during the stage of acute reactive cellulitis may lead to a flare-up with lymphangitis or spreading infection in the hand. It is always wise to wait until the acute inflammation is obviously on the wane before having recourse to amputation. In the case of patients who do not labour with their hands the finger should be preserved. The thumb is an exception to this rule and should always be preserved. The same rules should hold good when a joint is disorganized.

#### *SUMMARY.*

Early accurate diagnosis is the crux of the management of hand infections.

For lymph infection without suppuration the treatment should be on essentially conservative lines.

For suppurative infection in tissue spaces or tendon sheaths prompt and free drainage with early systematic functional exercises should be the guiding principles.

II.—O. MAX PAGE, D.S.O., M.S., F.R.C.S.,  
Surgeon to Out-Patients, St. Thomas's Hospital.

I THINK the opener has given a very clear exposition of the principles which should govern the treatment of these cases. I am glad he has emphasized their economic importance. A septic hand in a working man may easily lead to grave industrial disability, and I think all the more severe types ought to be treated as hospital in-patients during the acute period; it is the only way in which the all-important supervision can be obtained at this stage.

In regard to the opener's classification of types, I agree as to the clear distinction between what he calls lymphatic and cellular infections; but I think the term "lymphatic" so applied is misleading. There it is a common type of infection of the subcuticular layers of the skin which is frequently followed by mild lymphangitis and lymphadenitis. Such cases require careful local treatment by the complete removal of all undermined cuticle. Suppuration about the lymphatics or in the glands may occur later, but the constitutional disturbance is essentially mild. The severe cases are due to the inoculation of an unusually virulent strain of the streptococcus, and might be classified as fulminating streptococcal infections. In these cases little or nothing surgical can be usefully done in the first few days; the issue depends upon the patient's natural resistance to the bacterial invasion. This may be reinforced with antistreptococcal serum, but I think it is difficult to obtain crucial evidence of its value.

In the matter of the surgical treatment of cellulitis and suppurative teno-synovitis, the opener has given a clear outline of the anatomical points which should govern the position and extent of the incision. I think it important that the incision should be sufficiently free to allow it to gape. I do not think the tearing open of spaces with forceps is a sound practice in the presence of an acute infection. The surgeon's duty is to relieve tension and to inflict as little damage on the tissues as possible. I agree that the use of drainage tube or other foreign material is undesirable in theory, but in practice I pack the incisions for the first twenty-four hours with paraffin gauze in order to prevent the accumulation of blood clot and premature falling in of the margins of the wound.

The use of the tourniquet during operation on cases of this character has great conveniences, but it is not without its dangers. The experience of the war showed that the application of a tourniquet to a limb for an hour or two greatly prejudiced the course of an infected wound in the area which had been thus temporarily deprived of blood.

The dressing of wounds after incision for other conditions merits some consideration. Hot fomentations

are comforting to the patient, and may be allowed during the stage when great congestion is present. Their continued use brings the surrounding skin into an unhealthy sodden state, and predisposes to secondary infection of the wound. I think a dry sterile dressing, not too frequently changed, gives the best results in the resolving period. There is no doubt that the natural exudate is the medium in which defence and repair mechanisms work at their best. We have learnt this in regard to the peritoneum and the knee-joint, and may well apply the knowledge to the handling of acute infection in other parts of the body.

In regard to the restoration of function, I would draw attention to the importance from a prophylactic point of view of keeping the fingers partly flexed during the treatment of any palmar infection. This position will make it possible to break down or stretch adhesions which may form as healing proceeds. If the fingers are fixed in a fully extended position, no subsequent passive movements have any power to mobilize adhesions which will inevitably form.

When healing is complete movements under an anaesthetic may be carried out with care. In some cases a brisk reaction is provoked, which defeats the aim of the procedure. I think the use of graduated splintage to restore the movements of the fingers in both directions is a better and safer method, though requiring more time and patience. I have seen considerable general improvement in the mobility of the hand result from the use of hot paraffin baths.

I agree with the opener that when the flexor tendons of a finger have sloughed out, or when an interphalangeal joint has been infected, amputation is usually justified. In a few cases in which the scarring is not very extensive tendon plastic work may be worth while. In my experience attempts at arthroplasty on the interphalangeal joints are disappointing in their results.

### III.—F. D. SANER, M.B., B.Ch.CANTAB., F.R.C.S., Surgeon to Out-Patients, Royal Northern Hospital.

THE ideal treatment of these conditions, as elsewhere in the body, is prophylactic. In the majority of cases the serious septic conditions of the finger and hand arise from minute wounds or punctures, which are, perhaps, naturally neglected until inflammation becomes manifest. It is, no doubt, asking too much that every individual who pricks his finger should at once seek medical advice; though the public are more fully aware now of the possibilities of such a prick, and there exists a more or less deep rooted faith in the application of iodine or some antiseptic. If no organisms of virulence have been introduced, this application will have given a certain confidence and moral support, and no ill effect will accrue; but should virulent organisms have gained an entry, severe results will follow. I would urge every surgeon or pathologist, who when operating on a septic case, or carrying out a necropsy, pricks his finger sufficient to draw blood, to have the minute wound excised (not incised) at once, and the arm immobilized on the largest splint possible, until everything is seen to be quiet. If the excision be done at once, the wound may be closed; there is no advantage in leaving it open.

Such treatment may appear excessive; I do not believe it to be so, since if sepsis does perchance gain a hold, at the least it will entail some weeks of "off duty," while it may result in the complete removal of an active worker from his duties for good.

If infection has already gained a foothold it may be spreading along the lymphatics, cellulo-cutaneous tissues, in the blood stream, or in all three without pus formation, or it may become localized and be accompanied by pus formation.

The first group of cases present much the more serious and difficult problem, and by whatever channel the inflammation spreads, it passes far beyond the fingers or hand from which it originated. While all cases in this group are serious, roughly they fall into two types—the first, in which, though there is evidence of a spreading inflammation, the constitutional disturbance is not excessive, and a second

type in which the patient is ill out of all proportion to the local manifestations. In the first type, the value of immobilization of the whole affected limb cannot be overestimated; the splint used should be sufficient to ensure that this is complete. With the limb immobilized, and the patient at rest in bed, the natural defences are given their chance to localize the infection, and pus is liberated as it is formed. In the early stage, too, my faith has never wavered from the hot boracic fomentation, provided they are large enough and hot enough and aseptically applied, both as a means of producing hyperaemia and a comfort to the patient.

In the second type of case, when there are grave constitutional effects, when at the end of twenty-four to thirty-six hours from the first signs of infection the patient is seriously ill, it is probable we are dealing with organisms of extreme virulence or a patient with little or no resistance. In such cases not a minute is to be lost before relieving the areas of greatest tension by suitable incisions. Such incisions should not be indiscriminately placed, and should not open up the infected tissues which may be endeavouring to localize the spread.

Along the hand and arm the areas of greatest tension can as a rule be recognized and relieved by an incision which should penetrate the deep fascia. Such incisions, afterwards, can well be treated by Carrel's method of intermittent irrigation. The axilla presents a difficult problem. In these cases pain and throbbing is complained of in the axilla, and the glands are nearly always somewhat enlarged and acutely tender. These glands though under great tension, at the same time are an important line of defence. From the point of view of tension, as a source for further spread one may advocate that they should be excised, and that as a defence, though it is obviously an inadequate one, they should be left.

My own inclination is to leave the axilla untouched, chiefly because any excision would probably be incomplete, and it is impossible at the time to differentiate the useful from the harmful glands. Whatever operative procedure is carried out, afterwards, the whole limb must be completely immobilized. There is no doubt that in many instances serum is of the greatest benefit to these cases of generalized infection, but in my opinion it should not be relied on to replace the operative and splinting methods of treatment.

Fortunately, in civil practice it is rare to encounter a case of acute spreading gangrene; occasionally such cases occur, perhaps from injury to the hand, as a rule a severe one, and necessitate an immediate and high amputation of the limb as the only chance of saving life.

In the second group of cases, when the infection has become localized it will as a general rule be accompanied by the formation of pus. I should like to emphasize that the formation of pus is a kindly act and to be noted with relief; not that it means all danger is passed, but it does show that natural defences have been called into play and are offering some degree of resistance: pus is in itself harmless, except under tension. If pus has formed, it should be liberated by an incision to relieve the tension in that area. Such an incision should open up the extent of the abscess cavity, for which two or more incisions may be necessary, but it should not extend beyond the cavity, otherwise not only are the natural defences interfered with, but two new tissue planes are exposed to infection. Although relief of tension can be accomplished at the time, it is difficult to maintain. I am extremely doubtful of the value of so-called drainage tubes and gauze packing; on the whole, in my opinion they do more to defeat than attain the desired object. My impression is that so far the best method of maintaining relief of tension is the removal of areas of skin, subcutaneous tissue and fascia, or tendon-sheath if necessary—in order to produce a definite gap and not a cleft, the surfaces of which must needs be kept apart.

In inflammation or suppuration at the base of the nail, whether superficial or deep to the nail itself, the whole nail should be removed. Much time is often lost and suppuration prolonged by endeavouring to deal with these cases by incisions only or partial removal of the nail.

These are the fungi most commonly found in thrush. The botanical description of these fungi has been given in my previous papers as well as in the *Manual of Tropical Medicine* by Chalmers and myself. It suffices to say, from a practical point of view, that the fungi of the genus *Monilia* in the meaning of Pinyon and other mycologists, are characterized principally by the following features. In the lesions the vegetative body (thrush) is composed of mycelial threads of rather large size, often showing arthrospores, and numerous free oval or roundish budding yeast-like forms—in cultures, especially on solid media, mostly roundish or oval budding elements are seen, while mycelial filaments are very scarce or absent. These fungi, as a rule, ferment with production of gas, glucose, and often other sugars. The only *Monilia* I know of which do not attack any sugar or other carbohydrates are *Monilia zeylanica* Castellani and *M. zelandica* Castellani.

There is little doubt that the original fungus *Odium albicans* C. Robin 1853 belongs in reality to this genus, and its correct name is therefore *Monilia albicans* (C. Robin 1853). The term *Odium* or *Monilia albicans* has been used in the past to cover a number of different fungi, as proved by the widely different descriptions of it given by different authors. For instance, some observers state that the organisms liquify gelatin, others deny that it possesses such action. Certain authorities describe it as coagulating milk, others as not having any action on this medium, etc.

The more important *Monilia* fungi I have found in thrush may be separated into ten groups or types. The various types can be easily differentiated by their action on the following carbohydrates: glucose, levulose, maltose, galactose, lactose, saccharose, inulin, and dextrin.

Fungi of the first group (*M. balcanica* type) produce gas in glucose only.

Fungi of the second group (*M. krusei* type) produce gas in glucose and levulose only.

Fungi of the third group (*M. pinii* type) produce gas in glucose, levulose, and maltose.

Fungi of the fourth group (*M. metatuberculans* and *Monilia zeylanica* type) produce gas in glucose, levulose, maltose, and galactose.

Fungi of the fifth group (*M. tropicalis*) produce gas in glucose, levulose, maltose, galactose, and inulin.

Fungi of the sixth group (*M. guilliermondii*) produce gas in glucose, levulose, galactose, and inulin.

Fungi of the seventh group (*M. guilliermondii*) produce gas in glucose, levulose, galactose, and inulin.

Fungi of the eighth group (*M. pseudotropicalis*) produce gas in lactose, in addition to other carbohydrates.

Fungi of the ninth group (*M. pseudotropicalis*) produce gas in lactose, in addition to other carbohydrates.

Fungi of the tenth group (*M. zeylanica* type) do not produce gas in any carbohydrates.

Further details on the classification of the various species of the genus *Monilia* may be found in the *Manual of Tropical Medicine* (Castellani and Chalmers, third edition, pp. 1070-1092). It must be remembered that a certain number of fungi of the genus *Monilia* have not permanent sugar reactions, and therefore for purposes of classification and comparison such fungi should be investigated, using only recently isolated strains.

Fungi of genus *Odium* Link, *emendavit* Pinyon.—The genus is morphologically closely allied to *Monilia*, but mycelial threads are very abundant both in lesions and in cultures, and budding, yeast-like cells are rare. Fungi of this genus may occasionally induce an acid fermentation but do not produce gas in any carbohydrate. I have found fungi of this genus in certain cases of thrush in the tropic condition is not caused by one fungus only, but

If there is infection of the terminal phalanx of a finger, an incision removing an area of skin should be made along the lateral aspect of the finger, extending over the tip of the finger to the top of the nail bed; the phalanx itself may be removed wholly or in part, but personally I am not in favour of this as a primary measure, since if the relief of tension can be maintained, it is possible that only a partial necrosis may result. If the whole finger is involved with sloughing of the tendons and general destruction, I think immediate amputation of the finger is indicated, since there is no object in maintaining an area of septic absorption which eventually is going to be a stiff and useless object.

Suppuration may spread from a finger or fingers into the palm of the hand. In the early stages this may be arrested by incisions on the palm between the bases of the fingers. When there is pus in the palm of the hand, however deeply placed, an incision or incisions must be made to open up the whole area of suppuration. This may necessitate division and ligation of the arterial arches, and opening of the carpal bursae, and if so, it must be opened to its full extent by dividing the anterior annular ligament of the wrist.

After any operative procedure for the evacuation of pus, the whole limb is again immobilized on a splint.

In the after-treatment I do not think it is advisable to resort to too frequent dressings; immersion twice a day in a bath of hydrogen peroxide or eusol will assist in the removal of debris and sloughs which may block the exit, but, provided there is sufficient opening, such debris will gradually be cast out.

Splints should not be discarded until all active spread, as indicated by the local condition, pulse and temperature chart, has been arrested, and it is only then that movements of the fingers are to be encouraged. During immobilization the wrist should be kept slightly extended, and the fingers in their natural position of rest—namely, in slight flexion.

Once a tendon or a bone has become infected, no treatment will prevent destruction of a part of such tissue; nevertheless such destruction can be limited by the prevention of further spread. Ultimate movement of the fingers will depend entirely on the degree of destruction of their component parts, and complete recovery is impossible if destruction has occurred. Limitation by soft adhesions only, whether in the joints or tendon sheaths, may eventually be overcome.

Such, very briefly, I believe to be the main principles of the treatment of septic infections of the hand. The slightest indication of inflammation is to be treated seriously, while treatment itself consists mainly in the wise use of a splint and a scalpel.

#### IV.—G. T. MULLALLY, M.C., M.S., F.R.C.S.,

Assistant Surgeon, Westminster Hospital.

I PROPOSE to confine my remarks almost entirely to the immediate treatment of acute infections of the hand and more particularly to acute infections of the fingers. The less precedes the greater. Efficient early treatment of whitlow will almost completely abolish those terrible spreading infections of the palm which are so tragic in their results.

My purpose is to offer you, very briefly, a definite scheme of treatment in place of the very vague and unsatisfactory teaching which most of us have received. As a student and a house-surgeon I was told that the correct treatment for a whitlow was to open it. As to when to open it or on what principle to decide how big an incision was to be made I was left to find out for myself. I am sure that my experience is that of most of you. Whitlow, which in its economic results is one of the most important of the surgical infections, has been passed over by our teachers in favour of other conditions more interesting and dramatic.

I think it is possible to lay down a rational basis of treatment which can be applied with suitable modification to almost all acute infections of the fingers and hand.

It is necessary, when considering the treatment of a condition which is liable to cause so much suffering and to leave so much disability in its wake, to have clearly in mind

the essential features of the disease and a rational explanation of these features. With these as a basis, definite principles of treatment can be formulated.

The most striking feature of the disease is the frequency with which an infection beginning, apparently, in or immediately under the skin spreads to and involves bones, tendons, and tendon sheaths. This spread is a common complication of the cutaneous and subcutaneous infections of the hand—a very rare one in other parts of the body. To me this appears to be the essence of the problem.

What is the explanation? It is to be found, I think, in the anatomy of the hand and fingers.

The hand and fingers are made up of (1) a large bony skeleton, (2) a relatively large amount of almost avascular tendon, (3) skin which is closely applied to the bones, is thick and inelastic over much of its area, and is subdivided into small segments by numerous creases, (4) a very small amount of "soft parts" containing an unduly large share of dense fibrous tissue, the whole being richly supplied with arteries, veins, and lymphatics. These are the essential features of the hand when considered from the point of view of inflammation.

What happens when a finger becomes septic? The starting point is, let us say, a needle prick or a scratch on the terminal segment. This usually involves only the skin—sometimes it extends through the thick skin to the fat underneath—only very exceptionally is the bone or periosteum injured.

The usual phenomena of inflammation appear, pain being especially marked. Whilst the heat and swelling remain limited to the last segment the condition does not differ appreciably from any other superficial inflammation. In twenty-four or forty-eight hours, however, the inflammation spreads above the last crease and the second segment becomes involved in the swelling. The distal half of the finger is now swollen and distended to its full capacity and the tip of the finger is now no longer pink but cyanosed. This stage marks the complication of the inflammatory process by a new factor—that of strangulation. The blood flow through the end of the finger is being obstructed by the greatly increased pressure in the proximal portion of the finger. If this is allowed to persist thrombosis of the veins and lymphatics will follow and bring in its train death *en masse* of the more delicate constituents of the finger—that is to say, the bone and tendon.

The pressure to which inflammatory swelling subjects the vessels of the finger between the rigid bone and the tense hard skin is accentuated by another important point in the anatomy of the finger.

It is noteworthy that on opening a whitlow it is almost invariably found that the pus is limited in its upward spread at one or other of the phalangeal creases. It is unusual to find its proximal limit in the middle of a segment. This is because at these creases the skin is definitely attached by fibrous bands to the bone and consequently can stretch even less than elsewhere. As a result the creases have in the swollen finger the effect of constricting bands, and are comparable in their action to the constriction at the neck of a strangulated hernia.

It is, of course, obvious that the process of strangulation we are considering is progressive. Inflammation of the terminal segment begets obstruction to the blood supply and consequently a weakening of the antiseptic processes and a proportionately increased virulence in the infection. Spread to the second segment follows—the same vicious circle is set up and the first segment in natural sequence becomes involved.

Spread from the finger to the hand may and does occur through the action of the same factors. Fortunately, however, the space in the hand between the skin and the bones is large enough to allow of considerable swelling before any injurious pressure is exerted, so that it is only in the worst cases that direct spread takes place.

Infection of the hand from the fingers is more commonly due to spread along the tendon sheaths. These sheaths are in the fingers exposed to all the effects of the strangulation process and indeed help to increase it since they early become distended with fluid. As soon as organisms gain access to this fluid, whether by gangrene of the wall of the

and in the Balkans, but, so far, not in England. I have isolated three species: *Oidium maitlandiae* Cast., *O. asteroides* Cast., and *O. rotundatum* Cast. It is interesting to note that I have found the same species in cases of mycotic tonsillitis, while I have observed *O. rotundatum* and *O. asteroides* also in the stools of certain cases of enteritis. The description of these fungi may be found in previous papers by me, as well as in Castellani and Chalmers' Manual, third edition (pp. 1093-1096).

*Fungi of genus Hemispora* Vuillemin.—These fungi are characterized by the presence of abundant mycelial hyphae, some of which are conidiophores. Each conidiophore, which is called deuteroconidium. So far only one species of this genus has been found in cases of thrush: *Hemispora rugosa* Cast. This fungus was first isolated by me from a case of mycotic tonsillitis in 1910, and observed in a case of thrush by Piffier in 1915. Two varieties can be distinguished: one liquefying gelatin, the other having no such action on the medium. Botanical details of this fungus may be found also in Castellani and Chalmers' Manual (pp. 1108 and 1142).

*Fungi of the genus Willia* Hansen.—These fungi are characterized by the peculiar bottle-like shape of their ascospores. I isolated a fungus belonging to this genus in Macedonia from a case of thrush in a girl. In sugar broth it formed a thick pellicle containing air bubbles. It produced gas in glucose and lactose only. Old cultures on solid media contained asci with two to four spores of the peculiar hat-like appearance. The fungus seemed to be somewhat similar to *Willia anomala* Hansen, but the investigation of it is not yet complete.

*Fungi of genus Endomyces* Link.—These fungi are on superficial examination extremely similar to those of the genus *Monilia*, budding elements and mycelial threads being found in the lesions, and mostly budding elements in cultures. There is, however, a very important character which differentiates these fungi: in old cultures of endomyces asci are present. Only once have I come across a case of thrush due to a true endomyces, in Macedonia in 1917. I considered it to be *E. vulcanii* Landstein.

*Fungi of genus Saccharomyces* Meyen.—In the Balkans I found a case of thrush due to a typical saccharomyces, which I have only recently studied. Fungi of this genus are characterized by the vegetative body consisting only of budding elements, and by the presence of asci in cultures. The saccharomyces isolated by me fermentes with production of gas, glucose, lactose, galactose, maltose, and saccharose. It does not clot milk, which, however, may occasionally become acid. Gelatin and serum are liquefied.

*Clinical Varieties of Thrush caused by above Fungi.* I have always endeavored to study the cases of thrush I have observed both mycologically and clinically, to see whether different groups of fungi are causing different types of thrush. In my experience two principal varieties of thrush may be distinguished: (1) The white, or white-greyish type. By far the most common; characterized by the cream-white colour of the patches, and practically the only type of thrush found in temperate zones. (2) The yellow, or yellow-brownish type, characterized by the yellowish, occasionally brownish, colour of the patches. The first type may be caused by any type of the genus *Monilia* (except *M. reykianica* Cast. and *M. reykianoides* Cast.), by *Oidium maitlandiae* Cast., by *Endomyces vulcanii* Landstein, and by fungi of the genera *Saccharomyces* Meyen and *Willia* Hansen. The second type is caused by *M. reykianica* Cast., *M. reykianoides* Cast., *Oidium rotundatum* Cast., and *Hemispora rugosa* Cast.

*Constitution.*—Thrush is not caused by one species of fungus only, the so-called thrush fungus or *Oidium albicans* Robin, as generally stated. It is caused by a number of different fungi, some of which are botanically very far apart from each other, and belong to separate species, genera, and families. The term "thrush" covers in reality a group of clinically similar conditions, rather than one only; two principal types may be clinically distinguished, the white or grey-white type, extremely common, and the yellow or yellow-brownish type, of rare occurrence.

In the tropics bronchial affections due to the higher fungi are quite common, but in my experience they are also met with in temperate zones. I may perhaps be allowed to say a few more words about the following varieties: (1) Broncho-monilliasis, (2) broncho-mucormycosis, (3) broncho-aspergilliosis, (4) broncho-pentilliosis.

# BRONCHOMYCOSSES.

This variety of bronchomycosis was described by me in 1905 in Ceylon. The condition has recently been found in many tropical and subtropical countries, and even in the temperate zone. Piffier has described cases in South Africa, and Chalmers and Macdonald and Farna had a number of cases in the Sudan and Egypt, while Lacombe has found several cases in the south of Italy, and several cases have recently been observed in this country. The condition appears to be caused by several different species of the genus *Monilia*, which I have described on other occasions (see also Castellani and Chalmers' Manual of Tropical Medicine, p. 1866).

Clinically a mild type and a severe type of the malady may be distinguished, with, of course, a number of intermediate cases. In the mild type the general condition of the patient is good, there is no fever, and the simply complain of cough. The expectoration is mucopurulent, often scanty, and does not contain blood. The physical examination of the chest is negative or reveals only a few rales. The condition may last for several weeks or months, and may get cured spontaneously, or, continuing, may turn into the severe type. The severe type closely resembles phthisis. The patient becomes emaciated, there is hectic fever, and the expectoration is often bloody. The physical examination of the chest may show patches of dullness, fine crepitations, and pleural rubbing. This type may be fatal. The treatment consists in giving potassium iodide, with which glycerophosphates and balneum may be associated. It is interesting to note, however, that in certain cases potassium iodide has practically no beneficial action whatever. It is essential to differentiate primary broncho-monilliasis from secondary broncho-monilliasis, which is often found, for instance, in tuberculous cases. It is also necessary to differentiate pathogenic monilliasis from saprophytic monilliasis with identical biochemical characteristics. A pathogenic monilia isolated from a true case of bronchomycosis when injected into the lung of a rabbit will produce a most characteristic nodular condition of the lung, while a saprophytic monilia will not cause any lesion.

*Broncho-mucormycosis.* While I was in Macedonia a Serbian was sent to me with the diagnosis of tuberculosis. The patient was very anæmic, very weak, and was losing flesh rapidly; there was slight fever at night; the sputum was mucopurulent. Examination of the chest revealed nothing except a few coarse rales. Examination of the sputum for tubercle bacilli was constantly negative; instead, a few mycelial segments were noticed on several occasions. Glucose agar tubes and other media were inoculated and a fungus was isolated which at first showed cultural characters somewhat monilia-like; in subsequentures, however, the characters of a mucor appeared—a yellowish, ovoid-shaped, "comet-like," sporangium globular, elliptical and smooth. How did this patient get infected? It is interesting to note that he was in charge of horses and often had to remove horse-dung. As is well known, *Mucor mucedo*, L., is extremely common in horse-dung. I have seen several cases of this condition in the tropics, a case in an island in the Adriatic, another in Macedonia. These two cases had been diagnosed as tuberculosis from one *Aspergillus fumigatus*, *Aspergillus*, was grown; from the Macedonian case a fungus very similar or identical with *Sterigmatomyces nigra*, Cramer, was isolated. In France, as is well known, a peculiar bronchial aspergilliosis is common among pigeon breeders (*Quercus de pigeon*), who

sheath or by direct spread through the wall, they have a direct path leading them into the palm.

Infection in the palm of the hand gives rise to precisely the same phenomena as in the case of the fingers, but on a larger scale. The area available for the inflammatory swelling is bounded by the metacarpals behind and the skin and palmar fascia in front, with the anterior annular ligament and the creases on the anterior aspect of the wrist as a double constriction ring above.

In sum, then, the peculiarities of inflammation in the fingers and hand are due to their special anatomical features which give rise in the presence of inflammation to a process of strangulation.

The principles by which treatment should be guided in accordance with the pathology which I have very briefly indicated are clear and simple: restore the circulation by relieving the constriction and drain the abscess.

I propose to confine my remarks on technical details of treatment almost entirely to infections of the fingers. They are far the most common variety of hand infections, they are the almost invariable precursors of the more serious infections, and their efficient treatment will largely prevent the spread of infection to the palm.

It is a truism that any septic infection of the palmar surface of a finger constitutes a grave disease either actually or potentially. Unfortunately the public and many of ourselves have not yet realized this fact. A patient in the acute and early stages of a whitlow should be as automatically confined to bed as is the man whose hernia has just become irreducible. The affected hand should be put to rest on a splint and should be slightly elevated to assist by gravity the return of fluid from the swollen part. It

will be objected that this is a counsel of perfection and that patients will not submit to so much fuss over a simple poisoned finger." The criticism is probably just in many cases, but the same objection with as good grounds has been raised in the past over the treatment of many other diseases and has only gradually lost weight as we have persisted in our views and educated our patients.

Unfortunately it is only exceptionally that we are consulted at a very early stage of the disease. In most cases pus has already formed before we see them, and in the minority its presence, if not certain, is at least very probable. Where pus is present operation is, of course, imperative—where the presence of pus is doubtful we should be guided by the amount and position of the swelling. If a whole segment or more of the finger is swollen and hard operation is definitely indicated whether pus be present or absent—the chief aim of the incision being to relieve the tension and prevent or relieve strangulation. If the segment is not completely involved in the swelling it is permissible to wait, but if pain and swelling persist in spite of complete rest of the hand then operation should be undertaken.

The preparation for and details of the operation are, I think, of the utmost importance. In practically every case a general anaesthetic should be administered. Only a minority of doctors and patients have the resolution to perform and sustain an adequate incision through the acutely tender tissues of an inflamed finger. Freezing with ethyl chloride is in most cases no anaesthetic at all; infiltration with novocain is almost always unsuccessful in inflamed tissues and has the additional disadvantage of increasing the tension in the tissues and so adding to the danger of the strangulation.

A bloodless field is an enormous advantage in saving time and mess and in enabling the operator to see exactly what are the conditions present. It is readily and safely obtained by the use of a tourniquet above the elbow. With a tourniquet the operation field is changed from a welter of blood in which by continual sponging one gets an occasional glimpse of the tissues to one of comfort and precision. The full advantages are not obtained, however, unless the wound is firmly bandaged before the tourniquet is released. If this is done it is unnecessary to spend time picking up and ligaturing vessels.

The incision should be along the middle of the palmar surface. Its length will be determined by the conditions present. If the terminal segment alone is involved in the

swelling it should extend into the next segment so as to divide the palmar crease completely. If two segments are involved the incision should extend into the third, and if the whole finger is swollen the knife should be carried into the palm. If the palm is also tight and hard it should also be split to above the distal crease of the wrist. The object in every case is to divide whatever may be acting as a band of constriction.

There is no need to be frightened of long incisions either in the fingers or the hand; provided the underlying tissues have not sloughed the skin will eventually heal with an almost linear non-disabling scar. It is only by free incision that it is possible to relieve the tension and so arrest the spread of the infection.

In the finger the incision should be carried down to but not into the tendon sheath or periosteum unless they are already involved. In the palm the incision should divide the deep fascia.

When the tendon sheath is found to be infected it should be at once laid open—in the case of the middle three fingers to its termination in the palm; in the case of a little finger the sheath should be opened as far as the common sheath in every case. If there is not pus at the junction no more should be done for the moment—if pus is present in the common sheath it should be laid open as far as the anterior annular ligament. If the pus extends under this, the ligament should be divided and the sheath opened right up into the forearm. Where the incision crosses a nerve this should be identified—usually a simple matter when a tourniquet is used—and preserved as a bridge across the incision.

As soon as the exact condition of affairs has been determined the wound should be washed with saline and packed with dry gauze and firmly bandaged and immobilized on a splint. The tourniquet may then be released and the patient put back to bed with the hand elevated. Morphine should be freely given to relieve pain during the next twenty-four hours.

As regards after-treatment the tight bandage put on to prevent bleeding should be cut through within twenty-four hours, as otherwise it may exert undue pressure, and may give rise to much pain. The dressing itself should not be disturbed for forty-eight hours, and then only the outer gauze. The packing is best left undisturbed for seventy-two hours, when saline or eusol or peroxide baths may be instituted.

To recapitulate:

1. Infections of the hand are remarkable for the serious results which so often follow superficial and trivial injuries.
2. These complications are the result of a process of strangulation arising from the peculiar anatomical features of the hand and fingers.
3. Treatment should be primarily directed to relief of strangulation.
4. It is best carried out by free incision in a bloodless operation field.

V.—R. M. HANDFIELD-JONES, M.S., F.R.C.S.,  
Assistant Director, Surgical Unit, St. Mary's Hospital.

I PROPOSE this morning to confine myself entirely to the infection of various fascial spaces in the hand, which occur as complications in the course of infections of the fingers. I would first like to congratulate this Section on having chosen a subject—so often relegated to the realms of minor surgery—which has such a wide appeal to every class of medical practitioner, owing to the supreme importance of the hand in the wage-earning capacity of our people, and because, on the whole, the disasters which follow whitlows are more appalling than almost any major surgical procedure. Secondly, it is my great pleasure to express the indebtedness which surgeons the world over owe to Professor Allan B. Kanavel for his masterly exposition of the pathology, symptomatology, and treatment of the infections of the hand.

The spaces I would bring to your notice are (a) the middle palmar space, (b) the thenar space, and (c) the distal forearm space, if time permits; and perhaps I may be allowed

ing the war a Serbian soldier was sent to me with the  
specimens of tuberculous. He was wasting and had scrofin  
The expectoration was mucopurulent, and occasion-  
bloody. Examination for tubercle bacilli was con-  
negative. A few mycelial threads were present. A  
was grown with the characters of *Penicillium crus-*  
I have described during the last fifteen years—and  
not rarely have been mistaken for diptheria—  
y, tonsillar moniliasis, tonsillar idiomycosis, and  
at hemisporosis.

#### DERMATOMYCOSSES.

role played by fungi in diseases of the skin is of  
importance; it suffers to bear in mind the various  
phytoses, the blastomycoses, the sporotrichoses, the  
omas. It is interesting to note, however, that  
played by the higher fungi in dermatology has been  
recognized, not many decades ago most authorities  
them any importance, some considering such  
isms to be merely saprophytes, and others going so far  
to state that the so-called fungi found in the epidermis  
no hairs did not exist, these structures merely repre-  
a granular degeneration of the epidermal cells.  
affections may be separated to a certain extent into  
groups: (1) The trichomycoses. (2) The dermatomycoses  
all limit myself to saying a few words on five little-  
conditions I have investigated: aspergillomycosis  
beard, cryptococcosis epididymica, accladiosis, furu-  
cryptococcea, and pruritus ani of mycotic origin.

#### Aspergillomycosis of the Beard.

years ago I noticed on the skin of one of my bunge-  
servants in Ceylon several brownish dirty-looking  
spots, which looked very much like dirt. He told me,  
er, that they did not disappear on using soap. I made  
up and saw that these patches consisted of a large  
of budding cells which I believed to be saccaro-  
I found the same patches, not only in other natives,  
o in Europeans, especially on the chest and arms, and  
the condition "saccharomycosis epididymica," which  
I changed later into the more correct designation  
"cryptococcosis epididymica." I did not succeed in growing  
the patches, but the organism, ordinary  
will not remove the patches; and soap occasionally  
In obstinate cases the patches may be touched with  
of mentment may be applied. Cases of the same con-  
I have in recent years observed in the South of

#### Cryptococcosis Epididymica.

following reasons: (1) Staphylococcus vaccines do not induce  
any improvement of the lesions. (2) Potassium iodide has  
largely doses is most beneficial and may cure the condition  
as well known that potassium iodide has no action on  
staphylococcal infections, in fact it renders them worse  
but it has a specific action on many mycoses.

#### Pruritus Ani of Mycotic Origin.

The enormous number of different drugs, ointments, and  
lotions recommended in the treatment of pruritus ani  
clearly shows that the condition must be of very different  
etiological origin. This, as a matter of fact, has been  
recognized for many years, and several types of pruritus ani  
have been differentiated, including a bacillary type, certain-  
authorities believing the condition to be of streptococcal  
origin. I should like to call attention to a variety of  
pruritus ani which in all probability is of mycotic origin.  
During the last eleven years I have had the opportunity  
of examining and investigating 49 cases of so-called  
pruritus ani and in 8 cases (15 per cent.) I have given

#### Pruritus Ani of Mycotic Origin.

"The growth on artificial media (such as carrot, potato, glucose-  
agar) consists of many small roundish masses, which later on  
coalesce, and are covered by epimorphous formations, giving the  
prickly appearance, and consisting of erect, straight filaments,  
parallel to each other, or at times interlacing. These filaments  
are approximately 2 microns in diameter, and carry laterally  
spheroidal, articulated in size at their points of insertion. Most of  
these pseudomycelialia are 4 microns in length, and have a broad  
described by Bodin in certain species of the genus *Trichophyllum*  
(Mabeson, 1894). These pseudomycelialia become detached and  
develop by apophysis, and myceloid filaments are formed. Certain  
bright yellow crusts covering the ulcers. Occasionally gum-  
matous nodules and furuncle-like lesions are seen. The  
course of the disease is very long, and generally there is  
very little or no tendency to spontaneous cure. Potassium  
iodide when given in full doses is generally successful.

#### Furunculosis Cryptococcea (Folliculitis decalvans).

During the last two years I have come across three cases of  
of a peculiar pyosis, which is in all probability of mycotic  
origin. I will give elsewhere a complete description of the  
affection; I will limit myself here to only mentioning a few  
points in connection with it. All the three cases had been  
considered to be ordinary cases of chronic furunculosis, and  
wore treated with staphylococcus vaccine for many months  
without any definite improvement. The lesions in two o  
them were localized all over the body, forehead, and neck,  
case scattered all over the body in addition to the scalp  
In a well marked case one observes on the scalp some follicle  
cular pustules which may be flattened or conical, erect,  
pierced by a hair; in addition, fairly large baggy swelling  
may be present which later open by one or several openings  
The hair falls off and patches of baldness are left, and ar  
permanent. Lesions practically undistinguishable from  
logical examination gives the following result: A staphylo-  
coccosis is easily grown from all the lesions, but in addition  
using mycological methods, I believe the cryptococcus and not th  
staphylococcus to be the real cause of the condition, for the  
following reasons: (1) Staphylococcus vaccines do not induce  
any improvement of the lesions. (2) Potassium iodide has  
largely doses is most beneficial and may cure the condition  
as well known that potassium iodide has no action on  
staphylococcal infections, in fact it renders them worse  
but it has a specific action on many mycoses.

quite rapidly to define for you the limits of these fascial spaces, because they are not adequately dealt with in textbooks of surgery and anatomy.

#### *The Middle Palmar Space.*

This, the most important space in the palm, has the following boundaries: Posteriorly, the fibrous sheet overlying the interosseous muscles. Anteriorly, a fibrous sheet which separates it from the tendons of the ring and little fingers and their accompanying lumbricals and the extension of the ulnar bursa. Radially, a fibrous sheet separating it from the thenar space, being attached to the palmar fascia in front, and the fascia over the adductor transversus behind. On the ulnar side, it extends as far as the radial index of the fifth metacarpal; distally, it reaches the level of the inward flexion crease of the palm; proximally, it sends a small isthmus up beyond the wrist-joint into the forearm. In addition, distally, it has three diverticula corresponding to the three lumbrical canals.

#### *The Thenar Space.*

This has the following boundaries: Posteriorly, fascia covering the adductor transversus. Anteriorly, palmar fascia and the thenar muscles and the tendons of index finger and of the flexor longus pollicis. Radially, reaching nearly to thumb metacarpal. Ulnar side, a fibrous septum separating it from the middle palmar space. Distally, as far as the radial end of middle flexor crease. Proximally, as far as the carpo-metacarpal articulation of index.

#### *Relations of Spaces to Tendons and Each Other.*

It will be seen that the tendon of the little and ring fingers and their lumbrical muscles are in close contact with the middle palmar space; and those of the index finger and thumb similarly with the thenar space. The tendons of the middle finger occupy an intermediate position, but tend to have a more intimate relation with the middle palmar space than with the thenar. It will be noticed also that the two spaces are separated by a fascial sheet which is very dense in its whole length, except at the proximal part, where it is so thin that pus in one space can easily invade the other.

#### *Methods of the Infection of the Spaces.*

<i>Middle Palmar Space.</i>	<i>Thenar Space.</i>
1. From little finger tendon sheath (if not in continuity with ulnar bursa)	Index tendon sheath
2. From ring finger tendon sheath ...	From longus pollicis sheath
3. From middle finger tendon sheath	Middle tendon sheath
4. From lumbrical canals of little ring and middle fingers	Index lumbrical canal
5. Rupture of ulnar bursa ... ..	Rupture of radial bursa
6. Direct puncture wounds ... ..	Direct puncture wounds
7. Lymphatic spread ... ..	Lymphatic spread
8. From thenar space ... ..	From middle palmar space

A realization of these avenues of infection gives great assistance in the difficult task of diagnosis.

#### *Diagnosis.*

The diagnosis is obviously of very great importance, for if left untreated the infection will spread in almost every direction, except to the surface, with the most disastrous results to the eventual function of the hand. General symptoms are those common to all severe infections—fever up to 104°, restlessness, hectic flush of the cheeks, and in short a typical picture of toxic absorption. Next the source of the infection must be considered, and, as I have already shown, the site of the primary focus points to very definite probabilities in the infection of the spaces.

Locally we have the following symptoms and signs:

1. Pain limited to the area of the space involved. This is not so accurately limited as in acute teno-synovitis and in a day or two is apt to become less marked, owing to pressure of oedema on nerves.
2. Marked tenderness over area concerned.
3. Swelling (its location and degree) is the most helpful sign we have. In the thenar area, where there is no dense fascia the thenar eminence becomes ballooned in no mistakable fashion. In the middle palmar space the dense fascia prevents anything like the same aspect of distension, but it is enough to obliterate the normal concavity of the palm and, even more, to cause a slight convexity.

Swelling on the dorsum of the hand I wish to lay particular stress upon. Every infection in the palm causes swelling on the dorsum. The inflammatory process early reaches the webs of the fingers by way of the lumbrical canals, and thence spreads rapidly through the loose areolar tissues of the dorsum. Except in direct infections of the back of the hand, primary dorsal abscesses are extremely rare. This point needs special emphasis, because in many hands the dorsal swelling to the untrained eye appears to be the most prominent feature of the case. This is promptly incised, not once but several times, without the least improvement in the hand, and the real abscess remains undrained. In 99 per cent. of cases no incision should be made on the dorsum at all, unless it be to open the thenar space.

4. Position and movement of the fingers do not help much, save that the fingers tend to be semiflexed. They can, however, be moved without much pain and this serves to remove any suspicion there may be of acute teno-synovitis.

#### *Treatment.*

The spaces must be opened and drained. The middle palmar space is drained by an incision along one of the three lumbrical canals leading into the space—namely, those of the little, ring, and middle fingers. Usually one will choose that canal which is most obviously infected, either because it was the route by which the space became affected, or shows signs of having become the worst affected. If none of the three call for attack, the best approach is through the little finger lumbrical canal. The incision is shown on the slides; that on the ulnar side opens the space only, the other the space and lumbrical canal. The dotted lines show how these incisions may be combined with those opening the ulnar bursa and those opening the tendon sheaths of the fingers. The incision should not extend higher than the middle flexion crease. The tendons are exposed and under them, following the lumbrical muscle, is thrust a pair of artery forceps. The space thus being opened, a rubber tissue drain is inserted and general treatment instituted.

*The Thenar Space.*—An incision is made on the dorsum on the radial side of the index metacarpal, corresponding in length to the shaft of that bone. The lower margin of the adductor transversus pollicis is identified, and around this a pair of artery forceps is directed on to the palmar aspect of the muscle. They must not be pushed in beyond the middle metacarpal bone for fear of infecting the middle palmar space. The thenar space is then opened and is drained in the usual way.

VI.—J. E. H. ROBERTS, O.B.E., F.R.C.S.,  
Assistant Surgeon, St. Bartholomew's Hospital.

THE subject is so large that I shall confine my remarks to some points in sepsis of the fingers. First with regard to infection in the pulp of the finger. Charles Dorrance of Philadelphia has shown in an admirable paper that there is a closed fibrous tissue space in front of the terminal phalanx and that the arteries to the phalanx, with the exception of branches to its base, run through this space. Sebaceous and sweat glands run down into this space, and it is by the ducts of these glands that infection may gain entrance. In my experience direct infection by pricks, etc., does not occur in a considerable proportion of cases. The usual history is that at first a pricking feeling is noticed, and when the finger is examined the pulp looks a little more prominent, and feels hot; later it begins to throb. At this stage the veins are compressed within this fibrous sac but the arteries are still patent. At the end of twenty-four to forty-eight hours all throbbing ceases because the tension is now high enough to close the arteries, necrosis of the phalanx is now certain though the base of the phalanx escapes because its blood supply comes from outside the sac.

All cases should have general anaesthesia—gas is sufficient—and a tourniquet. An incision passing close to the end of the nail and continued down the sides of the fingers to within a short distance of the lower end of the phalanx provides perfect drainage by raising an anterior flap and avoids damage to the nerve plexus in the pulp of the

logical methods of cultivation, fungi of the genera *Epidermophyton* and *Trichophyton*—names, *Epidermophyton curvis* Castellani 1905 (= *E. inhumani* Sabouraud 1907) in 5 cases; *E. rubrum* Castellani 1909 in 2 cases; a *Trichophyton* not yet classified in one case. The condition may be compared to the well known *punctis interdigitalis* pedum, which is due to the localization in the skin of the toes of the genera *Epidermophyton* and *Trichophyton*. These fungi remain in a dormant condition for years, and apart from the pruritus they give rise to scarcely any other clinical symptom; as a rule there is no sign pointing to a fungous condition, but a slight desquamation may be present and occasionally fissures. A somewhat similar process takes place apparently in the anal-perianal region. Fungi of the genera *Epidermophyton* and *Trichophyton* are capable of localizing themselves there, giving rise to practically no objective symptoms, although on close examination not rarely small red indurated patches may be seen, and occasionally an eczematous dermatitis due to scratching may develop. None of my 8 cases presented acute symptoms of chronic rich (tinea curvis, tinea inguinalis) of the inguinal region, but 6 gave a history of having suffered from it years previously. Two of the positive cases were suffering also from *punctis interdigitalis* pedum; and in both cases *Epidermophyton curvis* was isolated from the scrapings of the skin of the toes.

In my experience pruritus and of mycotic origin has no tendency to spontaneous cure. The fungus remains in the perianal region indolently, practically dormant, but giving rise to severe pruritus which may stop completely for certain periods of time.

Treatment.—I have found that silver nitrate is often very efficacious (arg. nitr. gr. xv to spir. aether. nitr. ʒi). but it should be used with great care. An ointment containing one or two grains of chrysarobin to the ounce is sometimes very effective. This, too, should be used with great care. The cure of iodine may also be used. I have a potassium permanganate lotion (gr. xxx to the ounce) useful, and also an ointment containing salicylic acid and sulphur (gr. x of each to 1 oz. of vaseline). When an eczematous dermatitis due to scratching is present, it is better first to use a soothing lotion such as lead lotion, and then when the acute symptoms of dermatitis have disappeared the antieczematous treatment should be started.

#### DISCUSSION.

Dr. Cavaruzzi (Athens) said that he thought that not only in the tropics but in Europe also many more cases of fungus diseases could be found if they were looked for. Diagnosis was made principally by means of culture; it was not possible to find fungi in routine examination. Most cases were mistaken for tuberculosis or syphilis; an illustration of this was the finding of many cases of sporotrichosis and other mycoses in Paris during systematic research following the work of J. B. Berman and J. J. Jorgensen. An interesting point was the role of fungi in some cases of chronic ulcerative colitis met with in Greece. In one case of monilia was the causative agent.

Dr. Huxwell (Wrexham) pointed out that streptothrices and fungi were a much commoner cause of suppurative than had been generally recognized. He asked Dr. Castellani for information regarding the nature of the lesions of fungal infection in the kidney in rabbits, and the effects of vaccine therapy in human cases of infection due to fungi.

Dr. Decker asked Dr. Castellani if he regarded the biological method he had described for the identification of changes took place when sugars were heated in the presence of pepsine, leading often to the production of fermentable substances from which the organism could produce gas, though without action on the original carbohydrate. He suggested that the method had serious limitations since it was generally recognized that gas production was the most variable of an organism's attributes. In his opinion the

Dr. MacKenzie (Melbourne) sought information on the method might have merit in determining the purity of a sugar provided careful precautions were taken against the changes incident on sterilization.

Dr. MacKenzie (Melbourne) sought information on the apparently successful treatment of fungoid conditions of the skin by vaccines. The lung nodules in rabbits' lungs after intravenous injection of the fungus was stated by Dr. Castellani to be almost identical with tuberculous nodes, giant cells, etc.—it must be a very disconcerting result. He stated that fungoid pathological conditions must be much more common than they had any idea of—points raised by Dr. Castellani, and which he advocated as a means of differentiation as to whether the fungus was parasitic or saprophytic. He cited examples where these points applied. In his opinion the study of fungi in diseases should receive more general recognition, especially as diseases due to this cause appeared to be much commoner than was supposed.

#### Dr. Castellani's Reply.

In his reply Dr. Castellani stated that though fungal diseases were commoner in the tropics they were not rare in this country, being found frequently in patients who had never been abroad. With regard to colitis, the present tendency was to regard such a disease as sprue to be caused by a dietary deficiency, but the rothy character of the stools was caused by a monilia which might or might not be the cause of the disease. Dr. Professor Wilson he replied that not much structural change was found in the infected kidneys of rabbits, the lesions being caused by a blockage of the glomeruli and tubules by the fungus. In a general way the results of vaccine therapy were disappointing, but in cases of infection with monidia, actinomycosis, and streptothrices the results were often satisfactory. To Dr. Dukes he replied that the sugar and pepsone must certainly not be autoclaved together, and recommended filtration of the sugar solution to ensure sterility. He was of the opinion that the method might be of value clinically in the identification of excreted carbohydrate. To Dr. MacKenzie (Athens) he replied that though vaccine treatment was often disappointing, good results could be obtained by large doses of potassium iodide: 50 grains of potassium iodide should be mixed with 30 grains of sodium bicarbonate, and glycerine or syrup added to prevent the formation of a precipitate. Such treatment gave remarkably consistent results.

#### MEMORANDA : MEDICAL, SURGICAL, OBSTETRICAL.

##### HAEMORRHAGIC PANCREATITIS IN A BOY.

A youth aged 17 was sent in to the King Edward VII Hospital, Windsor, by Dr. Hornibrook of Gerrard's Cross, on account of a sudden attack of acute abdominal pain, which had come on four hours previously. His history gave little information, being only an account of vague epigastric discomfort for a few days.

Incision showed great oedema of the peritoneum of the lesser sac, but no fat necrosis. The pancreas was large, swollen, and infiltrated with blood clot. An incision was made into it and a swab taken for bacteriological examination. The gall bladder was dilated, and on being opened was found to contain thin faecal-smelling pus. The bladder was drained, but the boy died two days after operation. The culture from the pancreas and from the gall bladder yielded *B. coli*.

Pathological Notes by Dr. Elgood.

There was some loose blood and serum in the abdominal cavity, but no visceral inflammation and no peritonitis. The pancreas was greatly swollen and softer in consistency than normal; it was dark purple in colour, with thin strands of lighter colour. Section shows that this condition is not uniform, for while at the tail the consistency is softer than normal, but not greatly so, there is obviously a good deal of blood in its interstices, and as the

*Case 13.*

A man, aged 69, had noticed dryness of the throat for four months; the teeth were very foul and he smoked about 3½ ounces of tobacco a week. An epithelioma was found involving the left tonsil and extending to the anterior pillar and soft palate; the tongue showed leucoplakia. The growth was diathermized, an enlarged gland in the neck was removed for examination, and the external carotid was tied; the gland was found to be inflammatory. There was no recurrence one year and eight months after operation.

*Case 14.*

A very old gentleman, aged 75, was found to have a large epithelioma of the right tonsil, extending on to the mucous membrane covering the lower jaw. The patient refused to have the glands removed, but he consented to preliminary ligature of the external carotid, which was carried out, together with a thorough diathermy of the primary growth. The patient made a speedy recovery, and there was no recurrence one year and seven months after operation.

*Case 15.*

A woman, aged 71, had an epithelioma of the right side of the tongue and adjoining portion of the floor of the mouth, adherent to the lower jaw. There were enlarged glands in the neck. The growth was thoroughly removed by diathermy, and subsequently the glands were removed from both anterior triangles. There was

no recurrence one year and four months after the operation. It will be noted that this was a case of carcinoma of the tongue occurring in a woman.

*Case 16.*

A man, aged 38, was found to have a carcinoma occupying the whole of the right antrum. The bone was so extensively involved that it was found impossible to remove the tumour completely, and the growth was therefore scraped away with a sharp spoon, and the whole of the cavity subjected to diathermy. A fistula subsequently resulted, and it is hoped at a later date to close the fistula by a plastic operation. There was no recurrence over two years after diathermy.

*Case 17.*

A man, aged 64, complained of difficulty in swallowing for a month, and of pain in the region of the back of the tongue. He smoked 1½ ounces of tobacco a week, was a heavy drinker at one time, but had been temperate for the last ten years; he was in the habit of drinking very hot tea; his teeth were very septic. A carcinoma of the uvula and soft palate was found, involving the upper extremity of the anterior faucial pillars on both sides. The growth was freely destroyed by diathermy, and although no enlarged glands were felt, the anterior and posterior triangles on both sides were cleared out by "block" dissection. There was no recurrence two years after operation.

## REPORT ON A CASE OF DIABETES TREATED WITH INSULIN.

BY  
E. I. SPRIGGS, M.D., D. V. PICKERING,  
F.R.C.P., M.B.,

AND

A. J. LEIGH, B.Sc., A.I.C.

(From the Duff House Laboratories, Ruthin Castle, North Wales.)

The following observations were made in co-ordination with the scheme of work arranged by the Medical Research Council at various hospital centres.

A man aged 47 was selected as a moderately severe case of diabetes mellitus, who had been observed with some detail over a period of eight years. He was an officer in a Highland regiment and noticed thirst and polyuria a month after the outbreak of war; but he could, at that time, march twenty-five miles. Four months later (January, 1915) he went to Belgium, was speedily exhausted, sent home in February, and came to Duff House, Banff, in March. Since then he has been readmitted five times. He is accurate and conscientious, and has, in the intervals, followed the régime prescribed by his medical advisers here and at home.

In the eight years this patient has been observed under each of the three methods of treatment which have been in vogue in the present generation—namely, (1) restriction of carbohydrate, without restriction of other foodstuffs; (2) the fasting treatment, with subsequent restriction of all foods; and (3) insulin.

Table I gives the weight, state of the urine, the blood sugar, and the calories and carbohydrates in the food at the beginning and the end of each of his former visits to Duff House.

The ascertained maximum tolerance, without glycosuria, for calories and carbohydrate at each visit is shown in Table II.

TABLE II.—Showing the Maximum Tolerance for Carbohydrate and Calories on the same Five Occasions.

Year.	1915.	1918.	1919.	1921.	1922.
Calories ...	3,190	3,176	2,334	2,304	£35
Carbohydrate	56	61	166	127	25
Glycosuria ...	0	0	0	0	0

The table shows that the complaint was at first of a mild type and responded well to treatment; but the deterioration of tolerance is clearly seen. In the last two years especially the patient has found increasing difficulty in keeping anything like sugar-free. His present occupation is not exacting, entailing mainly the duties which fall to the lot of a country gentleman of moderate means and quiet tastes who looks after his garden and animals. But he had been less able to do work and had become progressively more miserable and depressed of late.

The insulin used at first for this patient was prepared here by one of us (A. J. Leigh), who had the advantage of seeing the method carried through at the National Medical Research Council laboratories at Hampstead, and would like to acknowledge his indebtedness to Drs. Dale and Dudley. The mode of preparation was that of Collip, modified by Dale and Dudley. In one point we varied the procedure; this was that we got the use of a small building at the slaughterhouse and minced the fresh pancreas directly it was taken out of the animal, adding the alcohol on the spot and transferring the mixture to the laboratory afterwards. On May 9th and

TABLE I.—Showing the Condition on Admission and on Leaving on Five Previous Occasions.

Date.	Weight in Kilos.	Glycosuria. Grains in 24 hours.	Ketonuria as Acetone. Grams in 24 hours.	Blood Sugar Percentage.	Diet.		Treatment.	Remarks.
					Calories in 24 hours.	Carbohydr. Grams in 24 hours.		
1915. March 24 ...	72½	15	Trace	0.17	2,800	25	Strict diet till glycosuria remained steady; then carbohydrate tests	
May 19 ...	74	4	Small amount	0.16 (May 17th)	3,030	80		
1918. March 16 ...	67	0	0	0.15	3,000	25	Returned for a week for observation	With steady restriction of carbohydrate urine had become sugar-free.
March 21 ..	67	0	0	0.12 (Mar. 22nd)	3,064	41		
1919. July 4 ...	74½	Trace	0	0.12 (July 6th)	2,934	73	Returned for further tests. Carbohydrate gradually increased	Tolerance had improved still further.
August 19 ..	70½	0	0	0.17	2,197	138		
1921. May 2 ...	62½	12	Trace	0.13	1,535	27	Fasting and limitation of total food	In interval fasting treatment had been started owing to much glycosuria and feeling out of sorts. Tolerance reduced, but good.
June 23 ...	62½	0	0	0.16 (June 24th)	2,393	105		
1922. March 21 ...	63	74	Trace	0.14	1,917	11	Limitation of diet (less drastic towards end)	More ground had been lost. Patient insisted on increase of diet beyond his tolerance, contrary to advice.
April 14 ...	63	86	0	0.26	2,555	63		

10th the insulin used was that supplied from the British Drug House. We tested this material on rabbits for comparison with our own insulin.

The details of the experimental period of administration of insulin are shown in the accompanying charts.

*Experimental Period.*

The patient had been continued for these observations, and a similar diet was continued for a fairly constant diet.

for the first eleven days (April 15th to 25th) it was fixed both in quantity and quality, except that carbohydrate was added experimentally on two days. The diet contained carbohydrate 17, protein 133, fat 98; calories 1,430. The carbohydrate addition consisted of 60 grams of white bread on the 20th and 23rd. The blood sugar was estimated hourly from 8 a.m. to 9 p.m. for the first five days—that is, fourteen times a day. Later it was taken three times a day—at 8, 12 and 6:30.

In the records of the case the following points are to be noted.

1. A reduction of the general level of the sugar in the blood after insulin was given, noticeable with 9 units (3 rabbit doses) in three hypodermic doses a day (see Chart A), considerable with 18 units in three doses, and later with 12 units in two doses a day. The effect was greatest four hours after a dose. With repeated meals the sugar was rising high again eight hours after a dose, though not so high as it had been on the same diet without insulin. The effect of the insulin was also definite the following morning, as the blood sugar, on a constant diet, was not so high when insulin had been given the day before. (Chart C; compare 8 a.m. blood sugar on 28th and 29th with that on the 19th, 20th, and 27th.)

2. On the addition of 30 grams of carbohydrate (60 grams bread) to the mid-day meal (April 23rd) immediately after the mid-day dose of 6 units of insulin (Chart B) the percentage of blood sugar rose sharply and remained high for three hours. The rise was of the same character as that obtained by giving the same dose of carbohydrate on a non-insulin day; it was, indeed, though not absolutely so high, relatively more pronounced on the insulin day.

1. A reduction of the general level of the sugar in the blood after insulin was given, noticeable with 9 units (3 rabbit doses) in three hypodermic doses a day (see Chart A), considerable with 18 units in three doses, and later with 12 units in two doses a day. The effect was greatest four hours after a dose. With repeated meals the sugar was rising high again eight hours after a dose, though not so high as it had been on the same diet without insulin. The effect of the insulin was also definite the following morning, as the blood sugar, on a constant diet, was not so high when insulin had been given the day before. (Chart C; compare 8 a.m. blood sugar on 28th and 29th with that on the 19th, 20th, and 27th.)

2. On the addition of 30 grams of carbohydrate (60 grams bread) to the mid-day meal (April 23rd) immediately after the mid-day dose of 6 units of insulin (Chart B) the percentage of blood sugar rose sharply and remained high for three hours. The rise was of the same character as that obtained by giving the same dose of carbohydrate on a non-insulin day; it was, indeed, though not absolutely so high, relatively more pronounced on the insulin day.

appeared wise to make additions to the diet in the form of protein and fat and not of carbohydrate.

3. The sugar in the urine (Chart C) fell from round about 50 grams a day to zero, reappearing when insulin was discontinued and falling again when it was resumed.

4. The acid bodies, expressed as acetone (estimated by van Slyke's method), totaled about 4 grams a day. With 12 units of insulin daily this was reduced to less than 1 gram. The curve of acid bodies shows a reduction, to be expected, apart from insulin, on the two days on which extra carbohydrate was given. The reduction of acidosis is shown also by the figures for the ammonia in the urine. The percentage of the total nitrogen in the urine which was in the form of ammonia fell from 7.4 per cent. to below 5 per cent.—a normal level—as soon as insulin was given, about that figure since, for over a year it had not been possible for this patient to take food of the value of more than about 1,600 calories a day without sugar appearing in the urine in varying quantities. With 12 units of insulin a day in two doses he took 2,500 calories with no sugar in the urine, or traces only. With 18 units he took over 3,000 calories with less than 10 grams of sugar in the urine. Insulin enabled him, therefore, to reach a new and much higher level of tolerance.

6. When insulin was given the nitrogen balance became positive. When insulin was omitted it became negative again.

7. With experimental increase of food, chiefly protein and fat, up to 3,500 calories—that is, above the normal level of tolerance with 18 units of insulin—there was a rise of

Chart C. The graph shows blood sugar levels over time. The y-axis is labeled 'Blood Sugar' and ranges from 0.0 to 0.10. The x-axis is labeled 'Time' and ranges from 0 to 24 hours. The graph shows a series of peaks and troughs, with peaks occurring around 8, 12, 16, and 20 hours. The peaks are labeled with 'NO INSULIN' and 'INSULIN 12 UNITS'.

head is approached the redness and softness increase, till the tissue is almost diffident in places. The cystic duct was dissected down, and at the commencement of the common duct a probe was passed down to the duodenum. Though this traversed the duodenum, it apparently did so by accident, for closer examination suggested that the duct itself was blocked actually when in the walls of the duodenum, the block being caused by a chain of small gall stones (the largest the size of a pea) which were readily apparent under the mucous membrane. The pancreatic duct was observed close up to the obstruction, but the entrance of the main duct into the duodenum could not be satisfactorily made out.

### HEAT-STROKE: HYPERPYREXIA: RECOVERY.

THE following report of a case of heat-stroke which occurred in my practice in the country, with no cottage hospital or motor ambulance in the district, is of interest, and may be of assistance to any practitioner similarly placed who has not seen such a case.

On July 12th, about 1 p.m., whilst on my rounds, I was called urgently to see a farm labourer, aged 67, who had collapsed on his way home from his work in the fields about a quarter of an hour earlier, and had been carried to his cottage in an unconscious and what appeared a dying condition.

I found him lying on a couch absolutely unconscious, with a grey, ashen face; the breathing was shallow and irregular; the pupils were pin-point and fixed, and conjunctival reflex was lost. His body skin was dead white and mottled. The mouth and tongue were dry and hard. The temperature in the rectum was 109° F. His pulse was rapid, irregular, and bounding. He looked as if he would die at any moment.

I had him stripped and placed on an improvised bed. I sent his employer, the farmer, in his motor car to the nearest town, six miles away, for ice. Meanwhile, I had him sponged and doused with cold water and gave him a high enema of a quart of cold water. This was partly returned, but after ten minutes his bowel commenced to act, and with the assistance of massage along the colon a large quantity of faecal matter was evacuated. On arrival of the ice, some half-hour or so later, I had him rubbed down with blocks of ice, a block of ice placed behind the neck, and an ice-bag, improvised out of a sheep's stomach, placed on his head. An interesting detail was that we had to wait for a sheep to be killed to get this improvisation; but this was available by 2 p.m. from the local slaughter-house, where they were on the point of killing at the time.

The village nurse then gave him a high enema of ice water, and this was continued (washing out the rectum with three or four quarts of ice water) for over half an hour. By this time the rectal temperature had dropped to 100° F., and the patient showed signs of improvement, though he was still unconscious; the conjunctival reflex had returned and his breathing had become loud and stertorous. A quarter of an hour later the temperature was 97° F. and the patient showed signs of collapsing; his muscles were twitching and his pulse had become very feeble.

I then gave him a hypodermic injection of strychnine sulphate gr. 1/60, digitalin gr. 1/100, and had him transferred back to the couch and wrapped in blankets, with hot-water bottles placed to his feet and legs. The shivering rapidly ceased and he lay quiet but unconscious; his pulse steadily improved. The mottling of the skin, too, soon disappeared, and the temperature rose to 99° F. By this time it was 3.45 p.m. I left him with instructions to sponge with ice again if the temperature in the rectum rose above 103° F.

I saw him again at 7.15 p.m. and found him still unconscious, breathing quietly but irregularly, with a fast, weak pulse. I again gave him a hypodermic as before, and his pulse gradually improved. The temperature had risen to 101° F., but was not increasing. At 9 p.m. I had him carried from the cottage to a shelter near by that had been used by a tuberculous patient in the adjoining cottage.

At 9.15 p.m. he was given a few drops of brandy between his lips, and this, with the cool night air, seemed to revive him, and he suddenly regained partial consciousness and was able to swallow a little iced water. He tried to speak but could only stammer, and then was violently sick, vomiting up dark, bile-stained fluid. After this he seemed better, and was able to understand signs. No further treatment was considered necessary then and the village nurse sat up with him during the night. When I saw him at 11 a.m. the following day he seemed to have almost completely recovered and had slept well. His face, which even late the night before had been grey and cyanotic, was then flushed red and he was able to talk easily and had no pain. The temperature was normal. During July 13th he was able to take some barley water and weak tea, and was given a diaphoretic mixture. He vomited several times during this day; the conjunctivae were slightly yellow.

On July 14th he complained of severe headache; the temperature was normal, pulse 74 and good, but the vomiting had continued. I then gave him castor oil 3 ss. in brandy, which had a very good result. On July 15th, except for some giddiness, he was quite normal.

The treatment, which I had applied many times in India, seems to have had markedly good results despite

the age of the patient and the improvised appliances. I think that had we attempted to remove him to hospital he would have died on the way. It is of supreme importance not to sponge with ice after the temperature drops below 100° F. in the rectum, and when this occurs to prepare against collapse by supporting the heart with digitalis and strychnine and hot-water bottles, and then to watch that the temperature does not again rise above 102° F.

Had the temperature not responded to the ice treatment I should have had recourse to bleeding, and if this failed, as so often it does owing to the viscosity of the blood, I should have given him an intravenous saline if possible. The recorded air temperature on July 12th was 92° F. in the shade, and this with a high reading of the wet bulb thermometer always spells danger from heat-stroke, as the main channel of heat reduction through evaporation of the perspiration is so greatly lessened. I should think, too, that the loaded state of the bowel helped to produce the catastrophe.

## Reports of Societies.

### PROBLEMS OF OBSTETRICS AND GYNAECOLOGY.

THE Edinburgh Obstetrical Society held the first meeting of its eighty-fourth session on November 14th, with the President, Dr. LAMOND LACKIE, in the chair. The officials for the current session were appointed, Professor B. P. WATSON being elected president. The retiring president, before vacating the chair, delivered his valedictory address.

Dr. LACKIE thanked the society for the honour done him in electing him to the presidentship two years previously, and acknowledged the support given him by the different officials. He referred to the losses sustained by the society in the death of various members, in particular Sir James Affleck, Sir J. Halliday Croom, Dr. John Craig, and Dr. J. W. Ballantyne. He then proceeded to review the progress made in certain branches of obstetrics and gynaecology during the past twenty-five years.

In spite of the great amount of work done the problem of eclampsia still seemed as far as ever from solution; while this was so the recognition of the value of conservative treatment with a minimum of obstetric interference had led to a diminished mortality. The conclusions to which the discussion on this subject at the congress in Liverpool in 1923 had led were briefly considered. The speaker still regarded veratrine as one of the most valuable therapeutic agents at their disposal.

Going on to speak of Caesarean section, Dr. Lackie said that within recent years the operation had become so safe that there was a risk of its indications becoming too numerous, and he was convinced that it was occasionally undertaken without sufficient justification. Certain indications for Caesarean section were shortly reviewed, special mention being made of its employment in placenta praevia, concealed accidental haemorrhage, and in heart disease. Recent improvements in technique were briefly discussed.

There had been no change of note in the actual mechanical operation of induction of premature labour, but the induction of labour at full time was a commoner operation than formerly. Every case going beyond the expected date of parturition demanded careful investigation; for the induction of labour in such cases pituitrin was of great value and was more often successful than when used at an earlier stage in pregnancy. The danger of indiscriminate use of the drug during labour was pointed out.

Reference was then made to the induction of pneumoperitoneum and the use of x rays, which in America was regarded by some as a valuable aid in the diagnosis of pregnancy. On similar lines radiography had recently been employed in the diagnosis of tubal patency, and had been carried out by Rubin's method of gaseous insufflation of the uterus and tubes. Kennedy had also located the site of occlusion by radiographic examination after filling the

Doct et Vetera.

THE FATE OF LAVOISIER.

Are all the famous sayings to be discredited? We are told that the French Guards at Fontenoy did not request the English to fire first, that Wellington did not cry "Up, Guards, and at 'em!" nor Camborne "The Guard dies but does not surrender," at Waterloo. Recently several attempts have been made to prove that the famous saying to the effect that the French Republic had no need of servants was apocryphal.

A note published on October 20th (p. 727), in which we quoted from the author of the paper under notice a list of martyrs to science containing the name of Lavoisier, has brought us the following letter from Dr. Arthur Lynch:

"When an error either in history or in science is repeated often enough it obtains a sort of official consecration, but that is not quite the same thing as the truth. This is apropos of your notice of Mr. Harry Cooper's article, in which Lavoisier is included among the martyrs to science. That was not the case. The great chemist was executed as a 'profligate.' He had married the daughter of a banker to whom public taxation had been farmed. The revolutionists were very bitter against this class, and it was in spite of, and not because of, Lavoisier's achievements in science, that he was guillotined. What then becomes of the famous saying, 'The Republic has no need of servants?' Nothing becomes of it, for it was never uttered. It was invented in a style the secret of which is still not lost by the Royalists, and used for propaganda."

We are disposed to agree that Lavoisier was executed along with the other farmer-generals because he was a farmer-general. But we are not on that account compelled to accept Dr. Lynch's sweeping denial of the story that the infamous Coffinhal, vice-president of the Revolutionary Tribunal, dismissed the illustrious chemist's plea for a fortnight's respite with the words "The Republic has no need of servants or of chemists." There is very respectable and almost contemporary authority for it and indeed every probability that the reply was actually uttered.

The farmers of the Revenue, of whom Lavoisier was one, were ordered by the Convention to produce their accounts. To do so fully was difficult or impossible because a great many of the necessary documents had been destroyed in the disturbances of the earlier days of the Revolution. In 1794 they were arrested before the Tribunal and condemned to death. The only charge that was at all seriously examined was that of having watered the tobacco, of which they had the monopoly, and thereby—it is to be supposed—having aided the enemies of France. They had done nothing worthy of death, but they were "aristocrats" and rich and their estates were to be confiscated.

In Volume XIV of the *Proces fameux jugés avant et depuis la Révolution*, par le citoyen Desessarts, published in 1797 (only three years after Lavoisier's death), we have an almost contemporary account of the circumstances.

Vice-president Coffinhal, who was the judge, was one of Robespierre's adherents up to the very last, and of Robespierre we are told that it was notorious that he hated men of talent and still more men of genius, and that it was this passion that Lavoisier owed his death. Marat also had a fierce grudge against Lavoisier as a man of science, as Michellet distinctly states.

"This great revolutionist," (in science) "Lavoisier, would not have been able to make his revolution, had he not been rich. It was for this purpose that he had desired to be a farmer of the public revenue. Far from assuming in this capacity a fiscal spirit, he advised the lowering of several imposts, maintaining that the revenue, far from diminishing, would increase. When appointed director of the powder-magazines, he abolished the vexatious custom of searching the cellars in quest of saltpetre. Lavoisier, far more known than the other farmers of the revenue, had to undergo along the whole of the too natural animosity of the people against that body, so fatal to the state. He had taken the principal part in a measure necessary for the salubrity of Paris, which then occupied the minds and excited the imaginations of men, the removal by night of the bodies that had been heaped together for so many ages in the cemeteries. The plan of the new wall with which the *Fort-Grande* surrounded Paris. Marat also attributed to him, without any proof, the plan of the new republica, which wanted with having wanted with that wall, to deprive the city of air, and stifle it. . . . His (Marat's) persevering accusations, reiterated in several ways, prepared the scaffold for Lavoisier. The latter, who plainly perceives that having done so much to do, and so much to do, his life is of inestimable value to the nation, by J. B. Baillet. (London, 1831).

world, never thinks of flying. He could never guess the fatal stupidities that could deprive science and mankind of so precious a life. And yet hatred, fomented by Marat, increased. He had been unable to annihilate Newton; so, to console himself, he is determined to destroy the Newton of chemistry."

According to Michellet, Marat held a theory of light which was to overthrow Newton's, but the French men of science easily disproved it. As Lavoisier was the most distinguished man of science in France, Marat had a spite against him. Michellet, of course, was an apologist for the revolution and anything, but a Royalist. He does not refer to the saying, "The Republic has no need of servants!" But he is clearly of the opinion that Lavoisier was guillotined because Marat hated him as a man of science. It may be objected that Marat was murdered ten months before the death of Lavoisier, but his influence survived him. As soon as Lavoisier was ordered to be sent before the Revolutionary Tribunal, he foresaw the fate which awaited him and asked for a fortnight's respite. "I need this time," said he, "to complete some necessary experiments in some important work in which I have been engaged for several years. I do not cling to life, I will sacrifice it to my country." The brutal Coffinhal, says Desessarts, "this tiger of human aspect, made this barbarous answer to Lavoisier: 'La République n'a pas besoin de savants ni de chimistes: le cours de la justice ne peut être suspendu.' This was Lavoisier included in the batch of (28) farmer-generals and condemned to death with them for having mixed water and harmful ingredients in the tobacco which the farmers sold." The same writer says that Lavoisier had rendered valuable service to the State in matters financial. He was called upon in 1791 to help in the reorganization of the national Treasury, in which he established such a system of accounts that it was possible every night to tell the exact position of the public balances. A financier, hated by Robespierre and by Marat, who had denounced him in his Journal, Lavoisier knew well that to be accused was to be guillotined. Marat, as Michellet says, aspired to scientific distinction, of which the French Academy considered him unworthy. In this there was cause enough for his prejudice against the great discoverer of oxygen. Marat was unfortunately a member of our profession, and there seems no doubt that he received the degree of M.D. from the University of St. Andrews. Marat did not pass an examination for the degree, which was granted on the recommendation of two doctors of medicine resident in Edinburgh, and probably did not even go to St. Andrews to receive it. Coffinhal had been a medical student, but he seems to have had no liking for the work, and for him we need not blush. He is described as being particularly repulsive in appearance and as being in the habit of bullying prisoners and making brutal jests. When any of the accused attempted to defend himself (Hold your tongue, it is not your turn to speak.) On one occasion he condemned a fencing-master to death, and looking hard at him he said, "Well, old cock, party that thrust if you can."

He seems to have been a burly and passionate ruffian, for when Hanriot, who commanded the soldiers of Robespierre's party, came to report his ill success, Coffinhal in rage and disappointment threw him out of the window—a way of marking disapproval which was surely excessive and certainly unnecessary. He escaped arrest for a time but was not long afterwards betrayed and executed. It poured with rain on his last morning, and many of the crowd used their umbrellas to thrust him violently in the chest, crying, "Hut Coffinhal, party that thrusts if you can!" While others shouted, "Coffinhal, Coffinhal, tu n'as pas la parole!" Our sense of justice may be gratified by reading of his fate, but the blood of all the ninety-six, including Robespierre, who perished in the affair of Thermidor, could not make up for the loss of the great chemist at the age of 50. The small gang of homicidal fanatics and ruffians who had usurped control of the Republic during the Terror had no right to speak in her name. Before and after this time the French Republic thoroughly appreciated the importance of science to the State.

See Michellet's *History of the French Revolution*, translated by G. Cock, (London: Bohn, 1832.) Vol. II, pp. 56-7. Edited, with an Introduction, by J. B. Baillet. (London, 1831).

organs with a 20 per cent. solution of sodium bromide under pressure.

Several recent advances in gynaecology were then considered. The treatment of dysmenorrhoea was still a vexed question. At the British Obstetrical and Gynaecological Congress which met in Edinburgh in April last very diverse opinions had been offered by those who took part in the discussion. Professor Blair Bell had made a plea for a more accurate study of the pathology of the condition and a clearer definition of the various causes of pain, and had shown that with some fault in endocrine balance underdevelopment of the uterus was often an important factor and might manifest itself in different directions. Blair Bell had urged that in such cases effort should be directed towards stimulating the ovaries and uterus to fuller development, and with this in view advocated the use of thyroid and ovarian extract. For one form of underdeveloped uterus—the coelocleate uterus—vaginal hysterotomy had been recommended.

A method of treating gynaecological disease which had within the last fifteen years come rapidly to the front was that of radiotherapy, with regard to the employment of which much difference of opinion had been expressed. As regards carcinoma, Dr. Lackie said that radiotherapy should be regarded not as an opponent of operation, but as an adjunct, or as an alternative where operation was contraindicated. The indications for radiotherapy in uterine fibroids, in chronic metritis, and in the uncontrollable haemorrhage of young women were shortly considered and certain contraindications and disadvantages discussed.

No branch of medicine had in recent years attracted so much attention as endocrinology. It had become recognized that many morbid gynaecological conditions had as their basis some aberration in endocrine function; as instances of such might be mentioned precocious or delayed puberty, certain of the menorrhagias of puberty and the menopause, and possibly certain cases of dysmenorrhoea and sterility. Our knowledge of the physiology of the ductless glands was as yet so incomplete that organotherapy was largely empirical and often disappointing. Undoubted benefit, however, followed the use of whole ovary extract in the artificial menopause, and that of *corpus luteum* in the nausea of pregnancy. The employment of pluriglandular therapy seemed more hopeful than the use of single gland extracts.

In conclusion Dr. Lackie said that with a fuller understanding of the physiology of the pelvic organs had come a more determined attempt to practise conservative gynaecological surgery, and he called attention to Giles's recent paper in this connexion. The importance of conserving ovarian tissue whenever possible was now recognized, and salpingostomy, the drainage of pus tubes, the opening up of occluded uterine ostia, and myomectomy were different operations the value of which had recently become appreciated.

A vote of thanks to the retiring President was proposed by Dr. HAIC FENCROX and seconded by Dr. FORDYCE.

## VARIATIONS FROM THE NORMAL TYPES OF HUMAN METABOLISM.

A JOINT meeting of the Manchester Medical Society and the Liverpool Medical Institution was held on November 7th at Manchester, with Dr. E. M. BROCKBANK in the chair.

Dr. C. J. MACALISTER said that medical men were constantly being brought face to face with conditions dependent upon imperfections of metabolism which were probably developmental or reversionary in origin. In the process of evolution man had attained to what might be regarded as an average physiological perfection, but variants from such a standard were frequently met with. Man's habits as to food must have undergone extraordinary alterations and his capacity for metabolizing almost any types of foods, whether animal or vegetable, had surely resulted from developmental changes in the modern as compared with the primitive types. The lower animals had fewer of these complexities; they were in the main carnivorous or vegetarian as the case

might be. Man's ancestry included both of these classes, and a falling back to prototype might accord to him a lessened capacity for mixed metabolism. Dr. Macalister suggested that dietetic variations of metabolism resulted from reversions sometimes towards a carnivorous, sometimes towards a vegetarian type of ancestry. Coming from a common stock the carnivora would have a latent or undeveloped vegetarian metabolism; the vegetarian primate type on the other hand would have a latent carnivorous one. That hypothesis would explain the possibility of there being an adaptability to new dietetic conditions on the part of the primitive man as he emerged from the vegetarian or primate stage of his evolution. The latent carnivorous metabolism would become more and more highly developed and by degrees the organs and secretions for a mixed feeder would become evolved. Attention was directed to an association in individuals presenting polymastia with the presence of a long spiral appendix, sometimes presenting a funicular opening and thus resembling what was normal in the anthropoid apes. Although they were generally mixed feeders, presenting in most cases full powers of digesting and utilizing vegetable foods, these people were truly reversionary so far as their protein metabolism was concerned, and their flesh-containing meals required to be taken at much longer intervals than was the case in the average normal persons. Examples of this condition were given, but it was emphasized that the dyspepsias resulting from living on conventional lines were not uncommon, apart altogether from any visible evidence of arrested development such as the polymastia referred to. These dyspepsias depended on deficiencies of metabolism and elimination which brought them into the broad categories of gout, or, in other words, they resulted from idiosyncrasies or imperfections of metabolism, which were probably reversionary and had to do with the absence of normal metabolic rest periods.

Perhaps the most puzzling of all metabolic problems were those dependent upon sexual aberrations, cases in which males presented some degrees of femininity or where females had or came to possess certain male characteristics. These cases were not uncommon and they developed at varying periods of life, but in the human being they never attained to the extreme degrees met with among poultry or among insects.

Although determination of sex took place at the time of fertilization this did not imply that there might not be subsequent intersexuality due to the inheritance possessed by every individual, whether male or female, of hormones belonging to both sexes. There were dominant hormones belonging to and ruling the sex of the individual, and subdominant or latent ones of the opposite sex. This had been proved by operations involving removal of the essential internal secretions which directly influenced those organs or parts which developed or were capable of developing after the operation; that was to say, that males who were castrated approached the female type, whereas the females after the removal of the ovaries approached the male type. Apart from the results of operation there was plenty of clinical evidence of the same kind indicating that there was intersexuality in both sexes.

Many years of clinical observation had suggested that not a few of the disorders with which they as physicians had to deal depended upon incoordinations of functions brought about by mixed or approximating sexual metabolism. These were evidently cases which might be regarded as neutral or in which the sex dominant was delayed at all events until a later period of life. An example of this was found in the very interesting variety of dwarfism designated ateleiosis by Dr. Hastings Gilford. Examples of this were shown and particular attention was directed to the case of a man, aged 40, who after growing normally until 7 years of age, thereafter grew in height very slowly until he was about 30 years old, and he retained the characteristics of childhood up to a few years ago when the dominant male secondary characteristics became developed. Other cases were referred to where intersexualities became manifested at a later period of life associated with what were regarded as hysterical manifestations. Certain epileptics probably came into that class, also cases presenting psychoses and neuroses of

## THE TRAFFIC IN DANGEROUS DRUGS.

Evidence continues to pour in from various sources and from many lands of the widespread abuse of cocaine, morphine, heroin, and other drugs of addiction, as well as of the subtle ramifications of the narcotics and highly profitable trade in these perious commodities.

In the Norman Kerr Memorial Lecture published this week (p. 1013) Sir William Wilcoxon retold to the Society for the Study of Inebriety the familiar story of how the prescription of drugs for benedict medical purposes has led to habituation and abuse. He endorsed the principles and administration of the Dangerous Drugs Act, which has been in operation in Great Britain since 1920, and added that other drugs

Indian hemp, sulphonal, and even paraldehyde and chloroform, were liable to similar abuse and might lead to various degrees of mental and physical degenera- tion. A Home Office Committee is investigating the relative toxicity and liability to abuse of cocaine and the substitutes which have been suggested to take its place, and we publish this week a preliminary note by

Mr. E. Watson-Williams on some experiments he has been conducting in the pathological laboratory of the University of Bristol with cocaine, norcocaine, stovaine, atypin, butyn, and atoxodrine; they have led him to conclude that the dose that causes serious symptoms bears a different ratio to the minimum lethal dose in the case of different drugs of this class. Thus in the case of cocaine it would appear that a small trac-

the case of cocaine it would appear that a small trac- alarming symptoms. He states that the proprietors have supplied him with notes of five deaths from the clinical use of butyn, and he urges caution in its application.

Dr. Courtois-Soubert of Paris, who has done so much to call attention to the dangers of cocaine, has recently published a paper, written in conjunction with Dr. Giroux, on the spread of the cocaine traffic and cocaine- mania, dealing especially with the social danger thereby created. The authors relate the story of the discovery of coca, and describe its physiological action and the

cocaine addict. The euphoric effects of cocaine are said to differ from those of morphine. While the latter confers a passive and voluptuous blissfulness, the former vouchsafes a sense of volition-exaltation, of expansive energy, and of triumphant personality. The mental alienation and moral perversion of the cocaine maniac are dramatically described; the tricks of the traders in the drug are disclosed, and their huge profits indicated. Suggestions are made for

increasing the penalties that may be inflicted on those engaging in the illicit traffic, for the better control of international commerce in cocaine, for an improved propaganda among medical men and teachers regard- ing its perils, and for the prolonged detention and treatment of its victims.

Meanwhile, from the international point of view, the suppression of this evil.

we have to record that at the fourth assembly of the League of Nations, which met at Geneva from September 3rd to 29th, forty-nine States were repre- sented, and delegates from the United States attended for the first time. Certain resolutions were passed dealing with the opium question and the Hague Con- vention; further pressure is to be put upon Switzerland, Persia, Albania, and some of the smaller American republics to ratify the Convention. Megeat was recorded that a number of the countries which are parties to the Convention have as yet failed to make effective the control of the importation and exporta- tion of dangerous drugs. A new conference was suggested to consider how to give effect to Part II of the Convention, which aimed at the suppression of the Convention, (that is, smoking opium, and at the reduction of the amount of raw opium destined for its production. Yet another conference was also fore- shadowed to consider again the restriction of morphine, heroin, and cocaine to medicinal and scientific purposes, and the limitation of the production of raw opium and the coca leaf to the amounts required for such pur- poses. As the date proposed for the first of these conferences is mid-July, 1924, and the second is to follow the first, it is evident that the object aimed at by the International Opium Convention of 1912—namely, the suppression of the abuse of opium, morphine, and cocaine—is not yet within sight.

It has been officially claimed that India has carried out the terms of the Opium Convention in spirit and in the letter. It is difficult to appreciate the justice of that claim. The Convention provided that the export of "prepared" (smoking) opium should be possible "or," as soon as possible "nevertheless India continues to export some 10,000 chests of opium annually, the bulk of which is used for smoking, a practice denounced by the Indian Government as "essentially a social vice."

Bishop Brent, the eloquent and able chairman of the first Opium Conference, addressing the Advisory Committee at Geneva on May 25th last, quoted "the

various types; Dr. Macalister regarded it as possible that gastric ulcer might have a similar origin, this impression being gained by the similarity which existed between the prodromal symptoms of that disease and those which frequently characterized the female climacteric of puberty.

#### *Lacrymal Obstruction.*

Mr. EDGAR STEVENSON read a short paper on lacrymal obstruction, and showed a number of lantern slides illustrating the anatomical relations of the naso-lacrymal duct, some features of the course of the disease, and the anatomy of West's operation. The main object of the paper was to point out that when naso-lacrymal obstruction had been definitely established the treatment by probes, styles, etc., was useless, and only converted obstruction into definite stricture, choice of treatment finally lying between excision of the diseased sac, or an endonasal operation, such as West's. He referred to some successful cases of the latter operation shown recently by Mr. Bride and Mr. Diggle, and suggested that the time had arrived when the ophthalmic surgeon must make himself acquainted with endonasal surgery.

#### *Surgery of the Small Intestine.*

Mr. FRANK JEANS read a paper on the surgery of the small intestine. He discussed the diagnosis of obstruction and the technique after excision of gangrenous bowel. He favoured a rapid anastomosis, as the cases with an enterostomy (whole calibre) starved quickly and often did not get well enough for the completion of the operation. He described a compromise between anastomosis on the one hand and, on the other, the Paul's tube method, to be used in the worst cases. Where there was much effusion of blood-stained fluid in the peritoneum he drained for twenty-four hours. He reviewed the factors contributing to post-operative paresis of gut, and attributed a large share of the blame to the pre-operative dose of castor oil, which he hoped would soon be obsolete.

### CYANIDE FUMIGATION.

At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine held on November 23rd, the President, Dr. R. J. REECE, in the chair, Dr. P. G. STOCK read a paper entitled, "Some considerations on the use of hydrogen cyanide and allied substances, with special reference to international preventive medicine."

The author, having given a précis of the history of the subject, pointed out that the quarantine regulations adopted by the United States in 1920 imposed a definite requirement that all vessels engaged in trade with foreign ports should be fumigated not less than once every six months for the purpose of destroying rats. The regulations also stipulated that vessels should be fumigated *simultaneously* in all parts, and laid down the gaseous agents which were authorized. The regulations recognized that the oxides of carbon are efficient for the destruction of rats, but as they do not kill fleas or other insects these gases are practically excluded, and reliance is placed on sulphur dioxide or hydrogen cyanide—more popularly spoken of as hydrocyanic acid gas. An amendment published last January adds cyanogen chloride gas mixture to the list of authorized agents.

Dr. Stock then described the various methods in use for carrying out fumigation with hydrogen cyanide or allied substances, illustrating his account with a series of photographs and diagrams. He emphasized the magnitude of the task of efficiently treating a large vessel and called attention to the revision of the United States quarantine regulations which allowed an extension of the period of six months for the compulsory fumigation of vessels in the case of ships complying with the following conditions: (1) Vessels constructed so as not to favour or encourage the harbourage of rats. (2) Vessels plying regularly between ports not infected with plague. (3) Vessels regularly carrying no cargo, or cargo of such a nature or so packed or stowed as not to serve as rat food or rat refuge.

(4) Vessels which have been regularly certified as loaded in stream from rat-free lighters or as complying with the regulations relative to fending off from docks, proper use of guards on lines and hawsers, raising or guarding of gangways and ladders, and docking at rat-free docks or wharves.

In the ensuing discussion, which was opened by Dr. A. K. CHALMERS and continued by Sir GEORGE BUCHANAN and Drs. WILLOUGHBY, WHITE, CHAPLIN, and KING (U.S.A. Public Health Service), there was some difference of opinion as to the relative merits of the sulphur dioxide and hydrogen cyanide methods. Dr. King pointed out that in the application of quarantine regulations a wide discretion was properly entrusted to experienced officers, that what was aimed at was the attainment of a practical result. There was no intention to force the cyanide process upon anyone. The sulphur method had certain disadvantages; its destructive action on property was largely dependent upon the amount of moisture present. The relative merits of the two methods had not yet been fully worked out, but it was of great importance that a trained personnel should be employed.

In his reply, Dr. STOCK observed that the danger of the cyanide process, so far as could be judged from past experience, had been a consequence either of gross carelessness or inexplicable neglect of simple precautions. Owing to the rapid diffusibility of the gas, the liberation of large volumes into the atmosphere at the conclusion of fumigation probably did not constitute an appreciable danger.

### PYORRHOEA: ITS PREVENTION AND TREATMENT.

At the meeting of the Odontological Section of the Royal Society of Medicine on November 26th, Mr. DOUGLAS GABELL presiding, a discussion took place on pyorrhoëa and its prevention and treatment.

Mr. J. G. TURNER said that he regarded pyorrhoëa as the result of an attack of various germs, chiefly of low virulence, on the alveolar and dental tissues. The germs harboured on the necks of the teeth and in the periodontal sulcus. Pyorrhoëa was a dirt disease, the dirt being germs and sticky food debris; in the absence of dirt, no general disease could produce pyorrhoëa. The first element in prevention was a healthy body, with the intestinal tract in good working order. The second was the use of a food which was not sticky. In view of the common use of fine ground sticky flour, the best thing he could suggest was that bread should be eaten stale, three or four days old. The dental arches must be as large and regular as possible, so that all forms of dental overcrowding were avoided. The teeth should be so arranged in these large arches that the neck of each tooth was cleansible in its whole circumference. The best way to obtain the necessary spacing was to extract the first permanent molars at the age of from 14 to 16, or earlier in the case of a quickly developing child. Malocclusion and traumatic occlusion did not frighten him in the least; the inevitable sepsis of the normal arch in the presence of our sticky food was a far more fearsome thing. For a cure he was sure that general treatment would not suffice, though in some cases it would ameliorate the condition. In local treatment, which was by far the more important factor, his objective was to clean, to render cleansible, and to teach the patient to clean. Properly to do the original cleaning, all tartar must be removed, and all rough fillings and overlapping edges smoothed away. The next step was to decide whether any teeth were to be extracted. Some teeth stood condemned by their looseness, some by the extent and inaccessibility of their pockets, and some by the extent of caries; extraction might also be necessary for drainage—that is, to ensure cleansibility. Alternate extraction was sometimes a useful method. If teeth eight, six, four, and two were extracted, and the remaining teeth rendered as nearly aseptic as possible, pockets could be dealt with by the excision of gum flaps, and a healthy mouth obtained; but even then, unless the patient was taught to clean every exposed tooth surface the recurrence of pyorrhoëa was only a matter of time. In cleaning the teeth the

from dilution by the addition of water. The latter practice may yield large illicit profit and is not easy of detection. The household may complain on occasion that on a particular day the milk supplied to him was "poor," but the vendor is always ready with some plausible excuse, and if a sample taken by an inspector and submitted to analysis is found to be so poor as to justify police court proceedings the vendor cheerfully pays the fine inflicted out of the hundred per cent. profit he has made by selling water by the pint at the price of milk. Or he may raise a defence by what is known as an appeal to the cow—that is to say, by pleading that the milk was sold as it came from the cow and was poor at the source. For many years the test of added water has been the percentage of milk fat in the milk examined. The Sale of Milk Regulations, 1901, made by the Board of Agriculture, laid down that "Where a sample of milk contains less than 3 per cent. of milk fat, it shall be presumed, for the purposes of the Sale of Food and Drugs Acts, 1875-1899, until the contrary is proved, that the milk is not genuine, by reason of the abstraction therefrom of milk fat, or the addition thereto of water." This standard has always been considered a low one, and in those few instances where a sample of milk drawn direct from the cow has been shown to be under the standard the explanation has been usually accepted that the animal had been poorly fed or that the inferior quality of the milk was due in some measure to the default of the dairy farmer, who might so arrange the diet of the cow as to increase the quantity of milk given while reducing its quality. It was, however, long the opinion of prominent agriculturists that diet does not perceptibly affect the quality of milk.

The difficulties in securing the conviction of a vendor who has sold milk containing less than 3 per cent. of butter fat have been increased since, in the case of *Hunt v. Richardson*, a Divisional Court of five judges by a majority of one quashed a conviction in the case before them the deficiency in milk fat was due to the manner in which the farmer had fed the cows with the object of obtaining a large supply of milk without regard to the quality, and that therefore the milk was not of the nature, substance, and quality demanded by the purchaser. The time was ripe, therefore, for settling the question in dispute by precise, scientific, and authoritative investigation. Such an investigation has been carried out at his farm near Basingstoke by Mr. Wilfred Buckley, C.B.E., who for many years past has concerned himself with improving the milk supply of the country and with educating the public in the importance of securing such improvement. The result of this investigation is embodied in a pamphlet recently issued by Mr. Buckley. The milk of each of 65 shorthorn cows was analysed each morning and evening during a period of thirty-nine days by Mr. Slim on behalf of Dr. R. A. Lyster, medical officer of health for Hampshire. The milk of each cow was weighed and the percentages of butter fat and of solids not fat in the morning's milk and in the evening's milk from the entire herd for each day, and for the entire period as well as for the

### CRIME AND INSANITY.

The Committee on Crime and Insanity appointed 1922, has made its report, and we publish elsewhere an analysis of its argument and the full text of the recommendations at which it has arrived. The Committee not consider that any drastic change in the law should be made; it advises that the famous rules made by the in *M'Naghten's* case should be maintained, subject to qualifications. The first is that a person charged with an offence is to be held irresponsible for his act if the act is committed under an impulse which the law with an offence is to be held irresponsible for his act was by mental disease in substance deprived of any to resist. The phrase "in substance" will undoubtedly, and has, indeed, already led in the daily news, to some criticism, since different interpretations are given to it by different judges. The other principle modification in the law is with regard to the which should be returned when a person is found irresponsible on the ground of insanity. The Committee recommends that the verdict should be that "the act (or made the omission) charged, but did the act (or made the omission) charged, but was guilty on the ground that he was insane so as not responsible, according to law, at the time." At the

milk of a herd of shorthorn cows "may be less than 3 per cent. in the morning but in all probability exceed 3 per cent. over a period of hours." With regard to the milk of individual cows the Committee states that the percentage of butter fat increases during the period of lactation; it is affected only slightly when the food is changed from winter rations to grass; it is often less than 3 per cent., especially in the morning; and that it should never be calculated for purposes on the basis of the analysis made during a period so short as a few hours. He is also of opinion that it is not to classify milk on the basis of butter fat content is now required by the Scottish Board of regard to certified milk, unless there be fat mixing the milk of the entire herd, analysing adding butter fat on occasions when the of fat is less than the prescribed amount, a which he believes to be impracticable. The of the discussion on pasteurization at the Milk Conference reported elsewhere in the (p. 1062) with regard to fat is that the process cause any diminution, although the amount that rises may be smaller when ordinary method used. The effect of pasteurization on the content of albumin and to render the calcium and phosphate more or less insoluble.

The results of Mr. Buckley's investigations quieting to those who are engaged in administrative work with respect to milk supplies, coming from so authoritative a source. He expresses that they will not have the effect of protecting individual who is so dishonest as to add milk that is offered for sale, but, as his right progress cannot be made on any basis that is to facts.

important thing was to get at the necks, therefore the brush covered only a small part of the ground. Waxed silk might be used, but this could only be drawn in the vertical direction; if used horizontally it cut into the gum. The best method was the use of worsted thread. Three-ply worsted was soft enough not to cut into the soft tissues, and thin enough to pass between the spaces of the teeth. After using the worsted he painted a weak tincture of iodine on the necks of all the teeth, but usually, as patients did not like iodine in the mouth, he followed this practice only every third day.

Mr. E. STURGEON said that he was astounded to hear Mr. Turner advocate the extraction of six-year-old molars. There was nothing more difficult to treat than a case of pyorrhoea with malocclusion caused by such extractions. The extraction brought about a change in the articulation which threw stress on the teeth, and the resulting condition could not be overcome by any local treatment whatever. If proper occlusion could not be secured there would always be pyorrhoea. He disapproved also of alternate extraction except where the alternate teeth were so diseased that there were no means of getting them healthy. In the treatment of periodontal tissue something more radical was needed than surface application of an antiseptic, and he claimed that only by means of ionic medication could the antiseptic be got into the tissues.

Mr. E. B. DOWSE agreed with Mr. Turner that pyorrhoea was a dirt disease. The teeth which should be extracted were teeth which were hopelessly loose or in which the pockets could not be obliterated or the pus removed. The first determining consideration in cure was the state of the patient's health; if this was bad, it was generally an indication for more radical rather than more conservative treatment of the pyorrhoea. He thought it a good sign if the bone was dense, with the skiagrams showing sclerosis around the margins, and with hard bosses to be felt in the teeth; such cases stood a better chance than others in which there was no bone reaction. The efficiency of mastication was another important point. If the occlusion was bad, mastication must be bad also, and therefore the best cleanser of the mouth was not functioning. Local treatment was all summed up in the term "efficient hygienic drainage." Every particle of calculus, especially subgingival calculus, should be removed by means of the best scaler obtainable, and the gums then freely excised. He judged the depth of the pocket and excised down to its base. In the subsequent cleansing any antiseptic or astringent would serve. He used various kinds, first one and then another, and if one of them appeared to lose its effect it was a good plan to prescribe another. It was very important also to teach the patient how to rinse the mouth. To cut spaces between the teeth in order to facilitate cleaning was, he considered, dangerous practice. The smallest space, if there was an interlocking cusp, would admit the fibres of meat and other food, which might set up severe trouble. Spacing, if practised at all, should be limited to those teeth on which there was no bite.

Sir H. BALDWIN did not quite agree with Mr. Turner's remarks on the inception of pyorrhoea. In his opinion the first thing to become inflamed was the immediate free edge of the gum; this became infected by the ordinary micro-organisms of the mouth when it was low in tone through the absence of friction. Friction of the gum, best done with the tooth brush, would prevent pyorrhoea. The friction acted chiefly by vitalizing the tissue. It was an essential part of prevention, and an integral part of treatment. He would never think of extracting the six-year molars to prevent pyorrhoea, and if Mr. Turner really intended young practitioners to follow him in this respect he thought his teaching dangerous. Ionization was a valuable method; if a little cocaine were employed with the solution the pockets were soon rendered quite insensitive, and advantage could be taken of their distension after withdrawing the cotton-wool to remove much unsuspected tartar. He did not think tartar was the cause of pyorrhoea; he had seen many cases in which there was no tartar. As an antiseptic he recommended nothing more than saline water.

Mr. COLIN KEAY did not agree as to malocclusion or traumatic occlusion being a contributory cause; in his

view it was one of the principal causes, and bacterial invasion was secondary. He always corrected malocclusion before scaling. Mr. F. W. BRODERICK believed the common factor in pyorrhoea to be a change in the equilibrium of the blood, a tendency to an excessive formation of alkali. Speaking with regard to disappointments experienced in vaccine treatment, he mentioned that Besredka, of the Pasteur Institute, had found that for cutaneous diseases—and pyorrhoea would come into this category—by painting a specially prepared vaccine on the skin much greater immunity was conferred than by injection into the blood stream. He had tried the method, and although he could not report the final results he found that the suppuration ceased almost at once, the inflammation of the gum subsided, and pain and discomfort were relieved. Mr. A. LIVINGSTON made the suggestion that whether worsted or any other thread was used, by tying a figure-of-eight knot it could be got into the little holes and made to scoop out anything that was there.

Mr. A. T. PRITS dissented from the view that traumatic occlusion was a factor in pyorrhoea and must be removed in order to treat the disease, although a very gross degree of malocclusion might play a part. If by the removal of the first permanent molars proper spacing could be ensured the practice might be justified, but very often it did not have this result, or what it yielded was the very slight spacing which was pernicious. He regarded it as a dangerous thing to advocate, and he also thought it dangerous to cut away spaces between the teeth.

Mr. F. N. DOWLE said that pyorrhoea could not be understood until it was known what were the different types of bacteriological infection which occurred in these pockets. Pyorrhoea was not a single condition.

Mr. FREDERICK HODDY spoke of the effect of friction of the teeth and gums from the veterinary point of view. Pyorrhoea, which was frequently met with in canine practice, was very rare among sporting dogs such as retrievers, which were accustomed to gnaw large numbers of bones, but it was common among dogs fed on soft food. He considered it a disease due to want of work for the teeth. It was also a disease of domesticity, rarely met with in creatures in the wild state. Dr. F. W. COLLINGWOOD believed that the disappearance of protective substances from the blood, and thereby the advent of pyorrhoea, was due to the want of balanced natural diet.

As many other members desired to take part in the discussion, it was decided that it should be resumed at the next meeting of the Section.

## NORTH OF ENGLAND OBSTETRICAL AND GYNAECOLOGICAL SOCIETY.

### *Encephalitis Lethargica and Pregnancy.*

A MEETING of the North of England Obstetrical and Gynaecological Society was held in Sheffield on November 16th, with Professor M. H. PHILLIPS in the chair, when Dr. HEND (Liverpool) described two cases of encephalitis lethargica associated with pregnancy.

The first case was a primipara, aged 24, who had no history of previous illness. The pregnancy was normal up to the thirty-sixth week. The patient then had headaches, albuminuria, and slight oedema of the ankles. She had treatment and showed signs of temporary improvement. A week later she had severe headaches, and a fit. When she was admitted to hospital her blood pressure equalled 150 mm. Hg, and she had albuminuria—9 grams of albumin per litre. There were no uterine contractions. The patient had six fits in six hours following admission—apparently typical eclamptic fits. Next day a living child was delivered. Later in the day rhythmic clonic contractions of the jaw muscles began. The temperature was slightly raised. The patient was restless and confused, and at the end of five days, as she was becoming worse, she was transferred to another hospital, where she died on the twentieth day after delivery. She had nystagmus, ptosis of the upper eyelid, and weakness of the facial muscles. On post-mortem examination the diagnosis of encephalitis lethargica was corroborated, and no evidence of toxæmia was found.

The second case was a primipara, aged 23, who had been healthy up to the thirty-fifth week of pregnancy. On admission to hospital she was restless and excited; she had inco-ordinated clonic movements of the head and limbs present during sleep. Her reflexes were normal. Albuminuria amounted to 2 grams per litre. Chorea gravidarum was diagnosed and she was treated with parathyroid extract, calcium lactate, and sedatives. On the fourth day after

TUBERCULOSIS IN FRANCE.

A MISSOURI DIPLOMA MILL

11,000 beds, for children suffering from surgical tuberculosis, in addition to institutions for lidotherapy in the mountains. The sanatoriums for pulmonary tuberculosis had 6,500 beds in all. The most popular establishments from the economic and social points of view were hospitals, but, unfortunately, the State did not contribute to the expense of setting them up. They were managed as hospitals, and received contagious and bed-ridden patients. In the sanatoriums proper the cases were rigidly selected. The main preventive establishments were the dispensaries, which now numbered 450, and their output was being made more complete year by year. In 1922 more than 40,000 screen examinations were made. The medical staff was recruited from doctors specializing in the study of tuberculosis. France had not nearly as many tuberculosis officers as England, but the number was increasing. Five hundred certified health visitors were attached to the dispensaries (150 of them in Paris), and the number would be 600 by the end of the present year. There were nine schools for the instruction of these health visitors, and to make the posts attractive, a pension scheme had been started. Examination at the dispensaries were very systematic; repeated examinations of the sputum were made—50,000 in 1922—and contacts were also examined. The dispensary was given except to necessary persons, monthly reports were made, and the graphic records and classifications were the same as in this country. It was not easy to estimate the effect of all this work upon the incidence of tuberculosis in France because the official collection of statistics ceased in 1918, but after five years' experience of the dispensaries some facts could be given. The mortality rate from tuberculosis at Lyons for the five years 1915-19, before dispensaries were in being, averaged 3.54 per 1,000 of population, but during the five years 1918-22, after the setting up of six dispensaries, it fell to 2.45. Even these figures did not reveal the full significance, for if the crowded working-class area of the town were taken, there also the dispensaries were concentrated, the mortality for the first period was found to be 3.61 and for the second 2.15. Dr. Ktvo added that the feeling of general practitioners towards the dispensaries is sympathetic, though occasionally they view with a little disfavour the activities of the health visitor. But the whole-time tuberculosis officer in a section of the department of the Oise had had in twenty-two months 1,502 consultations on new cases at the dispensaries, and 451 of these were sent to him by local practitioners. The problem of arranging for travelling dispensaries have been organized. The Grandeur-et-dual dispensary services was not simple. In some districts a system of boarding out had been widely adopted, and in twelve years 2,500 Paris children had been boarded out. The system, however, dealt only with children between the ages of 3 and 13, an effort is now being made to save children of an earlier age in affected homes, and despite the difficulty of the problem some headway is being made, thanks to the co-operation of the maternity services. Medical inspection in schools has been organized in most of the larger towns, and open-air schools have been started.

admission the patient was delivered of a stillborn child. The temperature rose to between 100° and 102° F. Diplopia was noticed on the following day. She had delusions, restlessness, and as she became worse she was transferred to another hospital. A diagnosis of myoclonic lethargic encephalitis was made. The patient was slowly recovering—four months later—but complete recovery was not expected.

Dr. J. CHISHOLM (Sheffield) recalled a case in a 2-para, with marked clonic movements of the abdominal walls and symptoms of internal obstruction. Caesarean section was performed; no obstruction was found and the movements continued afterwards. The patient was dull and apathetic. She recovered, but the child also had lethargic encephalitis. Dr. Chisholm mentioned another case with five and a half months pregnancy diagnosed at first as pernicious vomiting. Though labour was induced, the patient died. She had nystagmus in addition to the other symptoms.

#### *Supravaginal Hysterectomy and Panhysterectomy.*

Dr. FLETCHER SHAW (Manchester) read a paper on the advantages and disadvantages of supravaginal hysterectomy and panhysterectomy. He said that some gynaecologists believed that panhysterectomy should be done whenever the uterus had to be removed, while others believed that supravaginal hysterectomy was the better operation for many cases, though they would probably always do panhysterectomy if the cervix was badly lacerated. In a period of eighteen months he had had three patients in whom carcinoma of the cervix occurred after supravaginal hysterectomy, and his object in bringing the subject before the society was to see if other gynaecologists had had any similar cases. Although those three cases were seen in a period of eighteen months, they were the only ones he had ever had, and, so far as he knew, none of his colleagues at St. Mary's Hospital had had a single case; the occurrence after supravaginal hysterectomy was therefore very rare and it was probably merely a coincidence that he should get these three in so short a period. If that proved to be the case he still thought that there was a distinct use for supravaginal hysterectomy, as it was a much quicker operation and caused less shock to the patient and, moreover, did not entail opening the vagina, which, no matter how carefully cleaned, was potentially a septic passage. In a consecutive series of cases of supravaginal hysterectomy and panhysterectomy he found the mortality higher after panhysterectomy, and in the investigation of the convalescence of a consecutive series of both types the patients after supravaginal hysterectomy had, on the whole, a smoother time than those in whom the complete operation had been done. He still thought supravaginal hysterectomy was useful in nulliparous women, but panhysterectomy should always be done where the cervix was badly lacerated or in any way diseased.

The PRESIDENT said that he did not remember seeing carcinoma of the cervix after subtotal hysterectomy, but he had removed cervixes for discharge. He believed that panhysterectomy was the better operation in all cases.

#### *Cases and Specimens.*

Dr. W. W. KING (Sheffield) showed a specimen of carcinoma of the cervix which he had removed. The patient had had subtotal hysterectomy in 1919 for fibroids. In 1923 she had bleeding for three months, and the cervix was found to be carcinomatous. He recalled another case in a nullipara who in 1911 had gonorrhoea. In 1918 the patient had a pelvic abscess drained; in 1920 she had subtotal hysterectomy for bleeding, and six to eight months later she had inoperable carcinoma of the cervix. He believed in total hysterectomy in multiparae, and subtotal in nulliparae.

Dr. BRIDE said that in a case of a nullipara he had done a panhysterectomy and found an early carcinoma of the cervix. Dr. CHISHOLM mentioned a patient who had had a subtotal hysterectomy twenty-five years ago and who had bleeding for two months and was found to have inoperable carcinoma. She had had one child and one miscarriage. Dr. CLIFFORD said that he did not remember a case of carcinoma of the cervix occurring in his practice after subtotal hysterectomy. He said that it was so rare that it hardly affected the difference in the mortality rate

between the operations of subtotal hysterectomy and panhysterectomy.

Dr. J. BRIDE showed a tumour simulating complete ulcerated prolapsus uteri. He removed it from a 2-para who was pregnant four months. It was situated in the interval between the right labium majus and minus, and resembled an ulcerated complete prolapse. It had been noticed for twelve months and was steadily getting bigger. It was removed without affecting the pregnancy. Microscopically it was a fibroma.

Professor M. H. PHILLIPS showed (1) an adenomyoma of a rudimentary uterine cornu, and (2) salpingo-caecal fistula.

(1) The specimen was removed from a 7-para aged 44, who had had menstrual pain for the last seven years and recently pain not associated with menstruation. A swelling the size of a golf ball was attached to the left side of the supravaginal cervix and was diagnosed as adenomyoma of Gaertner's duct. At operation the swelling was found to be a rudimentary left cornu of the uterus attached to the supravaginal cervix, and also to the pelvic wall. On section of the cornu it was found to contain spaces filled with dark blood, lined by columnar or cubical epithelium, embedded in a cytogenous mantle similar to uterine endometrium.

(2) The specimen was removed from a 3-para, aged 32 years. Last child was born three years ago, and this was followed by severe abdominal pain for two weeks. She was admitted into hospital in November, 1922, suffering from a subacute attack of bilateral salpingo-oophoritis. Five weeks later she was seen again, when she had a fixed tender swelling to the right of the uterus which was thought to contain pus. Four weeks afterwards the swelling had disappeared and the patient felt much better. She was admitted in August, 1923, for dysmenorrhoea and backache. On examination a retroverted adherent uterus and slight enlargement of the appendages were found. The right tube was firmly fixed to the caecum, and the thickened area of the caecum was removed with the tube. The end of the tube was found prolapsed into the cavity of the caecum, the ostium being patent and well away from the opening of the vermiform appendix. The condition was thought to be the result of rupture of the peritubal pyocoele into the caecum.

Dr. BRIDE recalled a similar case in which an ectopic pregnancy had ruptured into the caecum. Professor M. H. PHILLIPS said that originally this case had been diagnosed as an ectopic pregnancy by the house-surgeon, but it had not occurred to him.

Dr. J. BRIDE gave the history of two consecutive pregnancies with central placenta praevia and Caesarean section.

A 2-para aged 34 was seen on November 20th, 1922, when she was found to be three months pregnant; she had a history of Caesarean section by Dr. Fothergill, whom he had assisted. A living child was delivered, who was still alive and healthy. On April 21st, 1923, the patient was admitted into hospital eight and a half months pregnant, with severe bleeding with central placenta praevia. Dr. BRIDE decided to perform Caesarean section; a living child was delivered, and at the same time the woman was sterilized by removing portions of both Fallopian tubes. The child died of convulsions on the eleventh day. Nothing was found to account for the placenta praevia habit.

Dr. STACEY said that it was very rare to have recurring central placenta praevia. Dr. W. W. KING asked to what extent the cervix was dilated; he criticized the second Caesarean section, and also the sterilization of the patient. Dr. FLETCHER SHAW said that one did not expect a Caesarean scar to stand difficult deliveries in future pregnancies. Dr. BRIDE said that the cervix was only slightly dilated; he did not consider possible rupture of the old scar. At operation the old scar could hardly be seen.

Dr. CLIFFORD (Manchester) related a case of full-time ectopic gestation.

A married woman was admitted to hospital on November 30th, 1922; she had had amenorrhoea since February, 1922. Foetal movement had shown that the child was active until two days before admission. She appeared to be at full term, the foetal limbs were rather prominent, the head high up and in the R.O.P. position. No foetal heart sounds were heard, nor any movement felt. The cervix was protruding from the vagina; the presenting part could not be definitely felt. A radiogram gave no assistance; the temperature was slightly raised; the cervix was cleansed and replaced and supported by a ring pessary. Labour did not come on and the patient was discharged at her own request on January 5th, 1923. She was readmitted on January 26th when the foetus was in the same position, and the temperature was slightly higher. Bougies were inserted into the cervix, but could only be pushed for 3½ inches. This was done twice. Her temperature was 102° F. and pulse rate 120. On January 29th and February 4th the patient had 4 minim doses of Dr. Jenkins's stock

residual vaccine. On February 14th Dr. Clifford opened the abdomen and found a full-term macerated foetus lying in a sac with the placenta almost entirely attached to the outer abdominal wall. This was stripped off without bleeding; the membranes were not removed, and the cavity was drained and irrigated by the Carrel-Dakin method for three weeks.

The cavity rapidly became smaller, and six weeks after operation there was a sinus 14 inches long. Inquiries afterwards revealed the fact that in March, 1922, the patient had severe abdominal pain with vomiting, followed a little later by haemorrhage lasting five days. Afterwards she suffered considerable abdominal pain, and in May consulted a surgeon, who thought she had had appendicitis. Dr. Clifford considered that the condition was very difficult to diagnose.

### LIVERPOOL MEDICAL INSTITUTION.

A MEETING of the Liverpool Medical Institution was held on November 15th, with the President, Dr. J. HILL ABRAM, in the chair, when Dr. HENRY COHEN read a paper on the value of hypertonic and hypotonic saline solutions in cerebral conditions.

After a brief summary of the experimental evidence on which this therapeutic method was based, Dr. Cohen recorded ten cases, six of cerebral tumour and four of post-operative cerebral hernia, in which marked alleviation of symptoms followed intravenous injection of 20 c.cm. of 30 per cent. sodium chloride solution. He commented on the oral administration of salt in these conditions, and on the use of hypertonic salines in the meningismus of acute infections, prior to cerebral operations, in the diagnosis of extracranial from intracranial causes of headache, and in the prevention of foramen crowding following lumbar puncture in cases of cerebral tumour. The value of hypotonic salines in post-puncture headache was also recorded. A discussion followed, and in replying to it Dr. Cohen pointed out that a considerable amount of experimental work had yet to be done, and suggested that ophthalmic surgeons should try these hypertonic salines in cases of increasing intraocular tension.

### Renal Sarcoma.

Mr. W. A. THOMPSON read a note on sarcoma of the kidney in an infant.

The patient was a female child, 15 months old, who was anaemic, emaciated, and had a large semi-solid swelling in the left lower abdomen. This swelling had been noticed for six months. It was moderately smooth in outline, there was no notch, there was dullness and bulging in the loin with colon resonance in front. The urine was normal and had apparently always been so. A renal sarcoma was diagnosed and operation advised. The operation was carried out through an incision to the outer side of the left rectus. The peritoneum on the outer side of the descending colon was incised and its edges brought up to the skin incision, and the operation was completed retroperitoneally. The child left hospital ten days later in excellent health.

Renal sarcoma appeared mainly during the first seven years of life; both sexes were affected with equal frequency, and the right side as often as the left. Occasionally it was bilateral. The clinical features in all cases were few and uniform—namely, a progressive, painless swelling in the lower abdomen, soon associated with increasing constipation and ultimately accompanied by emaciation. The sarcoma was thought to arise from the intrarenal adenomatous tissue which should have formed the convoluted tubules, but which, because of a poor blood supply, failed to develop normally and have taken on a tubulo-acinar formation. This became sarcomatous, and the growth, obliterating the calyces and renal pelvis, prevented secretion from the affected organ and thus explained the absence of haematuria, which was a common feature in these cases. The operative mortality was high, and of the late cases the majority of those who survived operation rarely lived twelve months. This patient made excellent progress for almost four months, when she contracted measles and died.

### Idiopathic Hypertrophy of the Bladder.

Dr. A. DROWALL FORDYCE and Dr. NORMAN CAPON read a paper on idiopathic hypertrophy of the bladder. Two cases of this condition were described, and lantern slides of the pathological condition exhibited. The analogy with

other apparently idiopathic neuro-muscular conditions was dwelt upon, and reference was made to the literature of the subject. At *post-mortem* examination of the condition the only pathological findings were hypertrophy and dilatation of the bladder, dilatation of the ureters and of the pelves of the kidneys, and cystic-like degeneration of the kidneys. There was no detectable cause producing the obstruction. The inference, corroborated by analogy, was that vesical spasm produced the local sequelae, and that it in turn was secondary sometimes to obvious nervous lesions, and sometimes to nervous abnormalities, which were not detected.

Mr. R. E. KELLY pointed out that the *post-mortem* picture of dilated bladder, dilated ureters, and dilated renal pelves showed a remarkable similarity to the condition found in adults with an enlarged prostate or a urethral stricture. The disease was limited to the male sex, and, therefore, the explanation that it was due to some neuropathic cause was a difficult explanation to accept. In his opinion there was obstruction. This obstruction was due to the constant and repeated blockings of the urethra by plugs of mucus. One had only to witness the pain, tenesmus, and straining in the living subject, followed not by a complete emptying of the bladder, but the passage of a small plug of mucus, to appreciate the enormous strain on the bladder. The increased tension inside the bladder produced the disease. It was a further example of the value of living pathology over observations made in the *post-mortem* room. In one case he had to withdraw a catheter two or three times and remove a plug of mucus from the eye of the catheter before he was able to empty the bladder completely. For this reason it was found impossible to wash out the bladder per urethram, for even after repeated washings under an anaesthetic mucus could still be detected by the cystoscope. In his opinion suprapubic cystotomy was the best treatment.

### ROYAL ACADEMY OF MEDICINE IN IRELAND.

A MEETING of the Section of Pathology of the Royal Academy of Medicine in Ireland was held on November 2nd, with the President, Dr. JOSEPH T. WIGHAM, in the chair, when Dr. A. R. PARSONS described a case of early Hanot's disease in a woman aged 31; *post-mortem* examination showed great enlargement of the spleen and thymus, congestion of the pancreas, and cirrhosis of the liver. Dr. GEOFFREY HARVEY described a case of splenic atrophy with thrombosis of the splenic artery in a woman aged 51; a large pleural effusion on the left side gave rise to the surmise that it was a case of early cancer of the lung or pleura, but no thoracic tumour was found at necropsy. Dr. H. C. C. DEANE described a case of tubal pregnancy; on *post-mortem* examination of the specimen the tube wall, in some of the sections, was seen to be infiltrated by the foetal cells, and small syncytial masses were found lying between the muscle fibres of the wall; it was uncertain whether to regard the condition as a simple tubal pregnancy or one tending to become a chorion-epithelioma. Dr. T. O. GRAHAM described an extensive case of intrathoracic sarcoma; at necropsy the growth was found to extend to the glands of the right side of the neck and to part of the pericardium, while the glands behind the stomach and pancreas were also affected. Dr. W. D. O'KELLY demonstrated a new method of making museum jars from celluloid.

At a meeting of the Section of Surgery of the Royal Academy of Medicine in Ireland, held on November 16th, the President, Sir WILLIAM DE COCKREY WHELLER, drew attention to the frequent coincidence of several cases illustrating rare conditions of the same organs being admitted to hospital about the same time. For example, within two years he operated upon three cases of abdominal aneurysm, but had never done so before or since. Four cases of fractured femur, with unusual complications leading to amputation, were recently seen. In September he had performed Leriche's operation of sympathectomy three times; and three cases of rare varieties of malignant tumour of the kidney had been seen during the past year. Mr. C. J. MACATELY read a paper on traumatic rupture of the liver and of the spleen, describing an interesting case of each; in the second case the spleen was completely torn off and temporary clotting of the blood vessels had saved the patient's life.

12.5 to 5, and in Switzerland from 11 to 2.12 during the same periods. In France the total number of deaths, which in 1906 was almost 5,000, was less than 1,916, or approximately a mortality of 7 per 100,000 inhabitants. In Spain the mortality has fallen from 44.1 for the quinquennium 1901-5 to 29 for 1916-20. The factors in the general decline in typhoid fever are purification of the water supply, removal of excrementitious matter by sewerage, notification of cases, supervision of foodstuffs capable of conveying infection, precision in diagnosis by serum tests, and progress in the hygienic education of the public. In countries where a fall in the disease has taken place as a result of these factors there is no necessity to employ much less to enforce prophylactic inoculation, except in the rare case of a circumscribed outbreak. On the other hand, in countries where typhoid fever is still very prevalent, inoculation is of the greatest value, and should be undertaken as far as possible by the public health authorities.

#### RESEARCH IN TROPICAL MEDICINE.

The annual dinner of the London School of Tropical Medicine was held on November 21st under the presidency of Sir Ion Hamilton Benn, deputy chairman of the Seamen's Hospital Society. In giving the toast of "The School" he said that it had been fortunate in having for its founders two such great men as Mr. Joseph Chamberlain and Sir Patrick Manson. From its inception twenty-four years ago the number of students had steadily increased. It was not content to teach the elements of tropical medicine to men who were going to tropical countries, but had encouraged research in its own laboratories and sent out expeditions to investigate diseases on the spot. Twenty such expeditions had been organized; Dr. Newham, director of the department of tropical pathology in the school, had only recently returned from British Honduras, and Dr. Thompson, director of the department of protozoology, blackwater fever. The chairman then referred to the expedition to Samoa, of which he gave some account last week (p. 995). In concluding his speech he made reference to the approaching transfer of the Tropical School to the School of Hygiene. Though the Tropical School might lose some of its autonomy it would retain its identity within the new school, and would benefit by close association with workers in other branches of preventive medicine. The toast of "The Guests," given by Sir Arthur Clarke, chairman of the Seamen's Hospital Society, was acknowledged by Sir James Allen, High Commissioner for New Zealand, who said that his Government rejoiced to have the assistance of the school in the discharge of its duties in the Pacific.

#### ROCKEFELLER INTERNATIONAL HEALTH BOARD.

The organization founded in 1909 by the initiative of Mr. J. D. Rockefeller under the name of the International Health Commission changed its name in 1916 to the International Health Board, and was first concerned with hookworm diseases, or, as it is usually called in America, ankylostomiasis, and for a million persons in the United States of America were examined microscopically, and of these 441,408 were treated; in 1915 the work of eradicating the disease was extended to other countries. The ninth annual report, for 1922, of the International Health Board contains a brief summary of its origin, and shows that, in addition to having measurably diminished hookworm infection all over the world, progress has been made towards reducing the ravages of malaria, and that

membranous conjunctivitis to another, or transmission of the infection by flies; the next most common source is a diptheria carrier with faucial, pharyngeal, and nasal lodgement. There was some evidence that the waiting room of the out-patient department had added to the number of cases. The authors remark on the rapid disappearance of the membrane after the use of antitoxin when the cause was a genuine diphtherial organism, in contrast to the lack of effect when other organisms were the cause. A considerable amount of albuminuria made prognosis bad. An outbreak of diphtheritic conjunctivitis which occurred in Assiout in September, 1922, and produced thirty-five cases, is described by Dr. A. M. Girgis. The local treatment employed was constant washing with eusol; quinine was tried but discarded as useless. Antidiphtherial serum was dropped into the conjunctival sac every two hours; silver nitrate was used as a paint once daily. The general treatment included tonics and serum injections (40,000 to 80,000 units). Of the patients attacked more than half (55 per cent.) were blinded; death occurred in 20 per cent. from heart failure. Dr. Meyerhoff records some observations on tuberculous eye diseases, which are rare in Egypt. "In general," he writes, "every case of very chronic iritis, with vitreous opacities and without pain, which does not react to aspirin and antisyphilitic treatment is suspect of being of tubercular nature. Unfortunately the tuberculin test . . . does not give a clear result. I know, through great experience gained in the war in Germany and Poland, where tubercular diseases have enormously increased, that the occult may sometimes obtain general tuberculin reaction in rheumatic iritis, and on the other hand I have seen in some patients the iris of both eyes full of tubercular nodules without obtaining any general or local tuberculin reaction." The cases seen in Egypt were for the most part mild, and reacted well to tuberculin injections. There are many other papers of interest in the bulletin. Some are in Arabic; it might be of service if a brief summary of such papers were given in English or French.

#### DIMINISHED INCIDENCE OF TYPHOID FEVER.

A year ago the Office International d'Hygiene issued a series of questions to the health authorities of the countries sending delegates to it. Information was asked as to the diminution of typhoid fever during the last thirty years, for opinions as to the causes of this diminution, and the practice as to antityphoid vaccination, and for a statement as to the need for antityphoid vaccination and its value. Replies were received by the Ministry of Health in this country from France, Holland, Switzerland, Denmark, Monaco, Sweden, and Spain. These replies have been analysed in a preliminary report by Dr. Ricardo Jorge, the director of public health in Portugal and the delegate of that country to the Office. The detailed replies are given in an appendix. Professor Jorge points out that in those countries in which compulsory notification is in force a marked fall not only in the mortality but also in the incidence of the disease. He gives the rates per 100,000 inhabitants. In Great Britain the incidence of typhoid fever has fallen from 38 in 1911 to 6 in 1922, and in Holland from 48.2 in 1892 to 16 in 1922. In Denmark the incidence was 150 in 1891 and 10 in 1921. In Switzerland it was 27.8 in 1901 and 8.6 in 1920, though there was a rise in 1904 to 37.9. In France the total number of cases, which was 31,206 for the two years 1912-13, fell to 15,815 for 1920-21. The number of deaths per 100,000 inhabitants has fallen in Great Britain from 17.3 for 1891-94 to 2.28 for 1916-20, in Holland from 17.3 for 1891-94 to 2.28 for 1916-20, in Holland from

## Reviews.

### PSYCHOTHERAPY.

IN *A Manual of Psychotherapy* Dr. HENRY YELLOWLEES sets forth first the principles upon which modern psychotherapy is founded, then its methods and their application, and finally the field in which these methods may be used. In the main the author follows the teaching of Freud, and he expresses the view that there is really no broad and comprehensive theory of the neuroses, and certainly no intelligible pathology of the neuroses, save on the foundations which psycho-analysis has laid. While he feels, however, that intelligent psychotherapy is wellnigh impossible without a knowledge of the postulates and principles of psycho-analysis, he is by no means of the opinion that exploration of the unconscious mind by the Freudian method is the only psychotherapeutic remedy of curative value.

Throughout his book Dr. Yellowlees shows that the general practitioner has a wide field of usefulness in dealing with his nervous cases by means of persuasion, suggestion, re-education, and simple analysis, and in his last chapter, where he gives some illustrations of the application of psychotherapeutic methods to actual cases, he maintains that the majority of these could and should have been treated by the general practitioner. The point is an important one, because there would seem to be little purpose in insisting upon the student receiving special training in the treatment of the psychoneuroses if such cases could only be beneficially treated by specialists and by complex procedures involving treatment for one or more years. Naturally many nervous cases require prolonged and expert treatment, but, as the author shows, many conditions arising in an average practice respond to measures of a relatively simple kind.

We can recommend this book as a useful introduction to psychotherapy. It is clear and readable and the author maintains throughout a commendable breadth of view.

### OPHTHALMOLOGY.

It is said by the more indolent kind of reviewer that it is sometimes possible to review a book from the preface, but certainly this would not be possible in the case of the encyclopaedic *Traité d'ophtalmologie*,<sup>2</sup> by Professor POULARD of Paris, for the preface consists of only ten lines. The author states that his book is largely the result of his own personal observations—it is not a reproduction of the works of others; flagrant errors have been rejected, matters of historical interest have been intentionally omitted, fantastic theories have been accorded their proper place, and hypotheses have not been presented as facts. The hope is expressed that the perusal of this book will stimulate the younger ophthalmologists to think for themselves and teach them not to be ashamed of holding their own opinions; in fact the preface suggests a more tolerant attitude towards the free opinions of the younger men than is sometimes to be met with among their more senior colleagues.

In its general arrangement the book conforms to the usual type. The first volume contains chapters on surgical technique, ophthalmoscopic examination, diseases of the conjunctiva, the cornea, the sclerotic, the iris and ciliary body, wounds of the globe and orbital trauma, the artificial eye, the eyebrow, the lids, the lachrymal apparatus, and diseases of the orbit. The second volume deals with refraction, affections of the lens, vitreous, choroid, retina, the optic nerve, the ocular muscles, and ophthalmological neurology. The index occupies fifteen pages and seems hardly commensurate with the size of the book. The work is essentially clinical in type, little space being devoted to anatomy and physiology, and not very much to pathology, more particularly the histological portions of that part of the subject, but the large number of illustrations and diagrams to a certain extent minimizes any drawback arising from insufficiency of printed description on these points.

<sup>1</sup> *A Manual of Psychotherapy for Practitioners and Students*. By Henry Yellowlees, O.B.E., M.D., F.R.F.P.S.G., M.R.C.P. Edin., D.P.M. Lond. London: A. and C. Black, Ltd. 1923. (Crown 8vo, pp. xv+247, 10s. 6d. net.)  
<sup>2</sup> *Traité d'ophtalmologie*. Par A. Poulard. Tome I et Tome II. Paris: Masson et Cie. 1923. (Roy. 8vo; Tome I, pp. 753, 402 figures, 3 plates; Tome II, pp. 699, 303 figures. Fr. 120 the two volumes.)

The three coloured plates deal with the plastic repair of the lids by turning in flaps of skin from the neighbourhood; there are no coloured plates of the fundus oculi. Figure 69 is labelled follicular conjunctivitis, but it looks much more like spring catarrh.

Conjunctivitis is conveniently classified as follows: contagious with secretion, superficial; contagious without secretion, interstitial; eruptive, non-contagious, and conjunctivitis following customary types—this chapter is particularly good; noteworthy also is the large amount of space devoted to syphilis of the membrane, a subject that is often treated rather superficially in the textbooks.

In the section on glaucoma the numerous newer operations for its relief are described and two excellent pictures of Herbert's small flap sclerotomy are given; in dealing with the trephine operation of Colonel Elliot the pictures are hardly so good—the conjunctival flap is drawn much too triangularly, and the trephine appears to have been placed purely on the sclerotic; it is only fair to state that in the description of the operation the necessity of dissecting a little way into the cornea after the conjunctival flap has been dissected down to the limbus is duly insisted on; the instrument illustrated seems to be the one devised by Stephenson, and not that of Elliot.

We have said enough to show that the book is a very good one; it is well printed and has an extraordinary wealth of illustrations. We have no hesitation in saying that we expect it to take its place as one of the standard textbooks on ophthalmology in the French tongue.

The appearance of the third edition of Meller's *Ophthalmic Surgery*,<sup>3</sup> edited by Dr. WILLIAM SWEET, is very welcome. This, the abbreviated title, is a little misleading, for the book does not make any pretence to go over the whole ground of ophthalmic surgery, but, as the title-page explains, is a description of operative measures recommended and performed in the great eye clinic of Vienna. Those who have ever taken out a post-graduate course in this world-famous clinic will be glad to have the methods which they learnt there kept fresh in their memory, and those who have not enjoyed the same advantages will be glad to read the descriptions of the operation which are usually performed at this clinic. We may say at once that the measures described in this book are all of them sound in theory; the degree of success attained depends upon the individual surgeon, and the results very often on the docility and behaviour of the patient. It is interesting to see how large a place local anaesthesia takes in ophthalmic surgery in Vienna; there seems to be little that cannot be done under a local anaesthetic, even Krönlein's operation. Meller rightly insists on a thorough knowledge of general surgical principles in anyone who contemplates taking up the study of ophthalmic surgery, and observes that attendance at operations as assistant helps the beginner materially. The instruction given comprises the correct demonstration of the proper method, and the analysis of accidents and mistakes. We are glad to see that throughout the book due recognition is given to this last matter.

The rest of the work is thoroughly sound, though some of the descriptions will hardly commend themselves to surgeons in this country; such, for instance, as the use of the keratome for making the section in iridectomy for glaucoma, and the advice given on page 205 that when the knife has been introduced for the section in cataract cases with the cutting edge downwards, if recognized immediately after the point of the knife enters the anterior chamber, the counter-puncture should be completed and the blade of the knife rotated as quickly as possible 180 degrees in its long axis, so that its edge becomes directed upwards. Meller states that the quick rotation prevents the escape of the aqueous, and that turning the knife in the wound is without disturbing consequences; we confess that we have never tried this manœuvre and we should be sorry to have to undertake it.

The book is well printed and the illustrations are very

<sup>3</sup> *Ophthalmic Surgery. A Handbook of the Surgical Operations on the Eyeball and its Appendages as practised at the I. Eye Clinic, University of Vienna*. By Dr. Josef Meller; edited by Dr. William Sweet. Third edition. Translated from the second edition, "Augenärztliche Eingriffe." London: William Heinemann. 1923. (Med. 8vo, pp. xv + 365; 225 figures. 25s. net.)

suggested above. These reasons will form the hypotheses to be tested by the results to be obtained during 1923, they will be confirmed if the results are similar to those obtained during the two previous years, which are the first two years of the present research."

#### WALLER MEMORIAL

As was announced last June, the friends, fellow workers and pupils of the late Professor Augustus D. Waller, M.D., and Mrs. Waller, have resolved to establish a memorial in recognition of their lifelong devotion to physiological investigation. The memorial is to take the form of a fund, to be used for the encouragement of scientific research. The fund will be administered by the Council of the London School of Medicine for Women, and Professor Waller was a lecturer in physiology where Mrs. Waller was first a student, then demonstrator and later a member of the council until her death, whose daughter is lecturer in physics. Dr. V. Waller was lecturer in physiology at St. Mary's Hospital Medical School for nineteen years, and it has now been suggested that an additional memorial should be established in the form of a research room to be called the Waller Research Laboratory in connexion with the physiological department. A committee has been formed, of which Prof. Winifred C. Cullis, of the London School of Medicine for Women, and Dr. J. S. Macdonald, Holt Professor of physiology in the University of Liverpool, are honorary secretaries. Professor J. Mellanby, of St. Thomas' Hospital Medical School, London, S.E.1, is acting as secretary. A subscriber who desires that his gift should be allocated to the St. Mary's memorial is asked to state when sending his cheque. It is hoped that a sum of £2,130 may be raised; towards this £1,300 has already been subscribed.

The committee of the Christie Hospital, Manchester, offers a prize of £500 for cancer research; the prize was awarded in two instalments. Its object is to support research already in progress, and it is hoped in this way to stimulate isolated work apart from the systematic work done by the cancer research institutions. The assistance will take into consideration promising work which is of value in medicine or in a science cognate to medicine, must submit evidence of original research work bearing cancer, done and protected. This competition is open to workers of any nationality, but all documents must be submitted in the English language. Applications should be sent to the Chairman of the Medical Board, Christie Hospital, Manchester, on or before December 31st, 1922.

On Wednesday, December 5th, a party of foreign medical statisticians, including delegates from Brazil, Bulgaria, Hungary, Czechoslovakia, and Russia, will be receiving Sir Walter Fletcher at the National Institute for Research at Hampstead. Dr. Brownlee and Dr. Greenwood have arranged for their benefit short discussions and demonstrations on statistical subjects.

The collection of drawings of war injuries of the Army Medical Museum by W. Wallace, late temporary captain R.A.M.C., is now on display at the Royal College of Surgeons of London, and available for study.

and in some cases 75 per cent. of the cases of malaria, are detailed. The report is in the State of New York. The report contains some remarkably good illustrations which show, among other things, the methods of treatment and instructions of the patients. The appendix contains much interesting information of a more technical character, such as details of treatment and a critical summary of methods of estimating the severity of hookworm infection by the hemoglobin index, worm counts, and ova counts. In another section of the appendix the methods of malaria control are summarized, including a description of Dr. A. Barber's method of killing the larvae of the topophilic mosquito by Paris green, which is especially useful in the case of waters so choked with vegetation that it cannot reach the larvae. In a short section on "Man-made malaria or man-made breeding places for anophiles," the causes, such as railways, agricultural irrigation, and drainage, responsible for 60 per cent. and in some cases 75 per cent. of the cases of malaria, are detailed.

#### MALARIA IN MALAYA.

The report on the Medical Department of the Federated Malay States for 1922 states that the estimated population in that year was 1,360,876, including about 6,000 Europeans. The birth rate for the year was 25.65, and the death rate 25.74, per 1,000. The death rate was the worst recorded for twelve years. The infantile mortality rate was 170.83, compared with 183 per 1,000 in 1921. The incidence of diseases from which death resulted were malaria (1.44 per 1,000), dysentery and diarrhoea (1.78), pulmonary tuberculosis (1.76), and beriberi (0.35). Malaria, as always, the most prevalent disease. There were 1,072 cases treated in hospitals, with 1,403 deaths and a death rate of 5.38 per cent., against 37,049 cases, with 1,943 deaths and a death rate of 5.24 per cent., in 1921. Free clinics are always available, and is distributed throughout the country through the medium of subordinated native medical assistants, police stations, and schools. On the advice of the Malaria Advisory Board each patient who has suffered from malaria in hospital is given a certain number of quinine tablets to take away on discharge. Cinchona bark is also used in some hospitals and shows good results—in some cases better results than quinine. The following figures relate to field and laboratory work in connexion with anopheline mosquitoes carried out by the Malaria Bureau during the year under review: Breeding places described 941, larvae identified microscopically 71,421, adults described 1,327, adults tested for egg-laying capacity 1,257. Observations were continued throughout the year to determine whether the various species of anopheline mosquito have definite breeding season or whether they are capable of breeding all the year round. In connexion with these observations the malaria research officer, Dr. H. P. Hacker, draws the following conclusions: "At the present stage it is impossible to base definite conclusions on the work in hand, but certain temporary deductions can be made. In last year's report it was stated that 'no definite correlation between species and the rainfall could be established,' and the main reason for this statement was

good; the translator might have taken more pains, to make his English easy reading; without being over-fastidious about split infinitives, a protest against the large number in this volume may be permitted.

One of the most useful of the smaller monographs on his subject to the ophthalmic surgeon is the handbook on *Perimetry* by Dr. LUTHER C. PETER, and we welcome the appearance of the second edition.\* The text has been recast to a certain extent; for instance, the section on the anatomy and physiology of the visual pathway has been transposed from Section III to the opening chapter; this is an improvement, for it is essential for the student to get a good grip of the anatomy and physiology of the subject before he enters on the study of the diseases. The new edition contains about fifty more pages and roughly forty more illustrations than its predecessor. For those who do not already know the book we may say that it is arranged under the following sections: anatomy and physiology; physiological principles and normal fields; methods, instruments, charts, and technique of field taking; general pathology of the visual field; special pathology of fields; fields in functional nervous diseases; and an appendix. The contents are thoroughly up to date, and it is pleasing to find proper recognition is accorded to the work of Gordon Holmes, Sir William Lister, Traquair, and Sinclair, in advancing knowledge of the cortical representation of the macula and in quantitative perimetry. An extensive bibliography completes a book which is singularly well produced; the paper and print are very good; there is a wealth of illustrations. It should find a place in the library of every ophthalmic surgeon.

#### WOMANHOOD AND HEALTH.

DR. CHRISTINE MURRELL has compressed into her little book, *Womanhood and Health*,† an enormous amount of information. The five chapters deal with reproduction from the biological standpoint, the organs of reproduction and their functions, menstruation, the laws of health specially applying to women, and suggestions to parents and teachers as to the methods of instruction for the young. The book is based on lectures given to many audiences during the last twenty years; and this no doubt accounts for the sense of compression induced in the reader. Dr. Murrell's aim is to give women sufficient information with which to test for themselves the various forms of advice they will inevitably be given, and to separate the wheat from the chaff. She is concerned also to show that the average woman is a normal, healthy individual, and that the mid-Victorian idea of semi-invalidism as the usual lot of women should be discarded. This thesis is developed chiefly in the chapter on menstruation, in which the investigations of several women doctors are quoted to show that the human organism works in a cycle of three to four weeks, and that the cycle is common to both sexes and bears no necessary relation to the menstrual period. Rather is it suggested that the change in emotional tone is due to alteration in blood pressure and not to the onset of menstruation. Some authorities, however, appear to admit that "owing to the probable emotional instability there is a natural tendency to 'feel sorry for oneself' " at the menstrual period, "and that this should be combated." The conclusion is drawn that menstruation should be regarded in the same light as the other recurring functions of the body, such as sleep, the taking of food, or the daily action of the bowels, all of which are not considered to imply any indisposition or departure from normal health. "It is of the first importance that women should recognize that they, no less than men, are normal healthy individuals," and "that the emotional cycle is a joint inheritance which they share with men, and is no true gauge of mental efficiency." The recognition of the truth of these propositions is

regarded as important because in these days so many women have to compete for work in the open market, and menstrual disability would prove an insuperable obstacle to their success. Dr. Florence Meredith of New York is quoted as reporting that dysmenorrhoea has decreased enormously in recent years, and the decrease is attributed to (1) improved attitude of mind, (2) increased general activity with no remission during the period. How small the effect of menstruation need be on the general activities is shown by the fact that the majority of women find that they can continue to take baths during the period without any ill effect and with much additional comfort.

Notwithstanding these views Dr. Murrell seems at times to be stricken with the thought that things are not quite so simple with women as with men, as when she states that the gradual cessation of the powerful ovarian hormone at the climacteric "tends to produce a temporary emotional instability of depression. This depression is much diminished if its cause is understood, and at its worst it need only be regarded as a dark tunnel through which the woman must pass in order to emerge into the calm daylight of peaceful later years."

Dr. Murrell gives much sound advice on the laws of health applying to women, though the modern scientific prohibitionist may object to her statement that "alcohol is a stimulant, and should only be taken as such." In the chapter on instruction for the young a difficult subject is tactfully dealt with.

#### COLITIS.

*Les Colites*‡ contains the collected instruction given in a course of lectures at the Beaujon Hospital, Paris, under the direction of Professor PAUL CARNOT, who has written an interesting introduction and himself describes amoebic and other parasitic forms of colitis. He argues that, contrary to some suggestions, the colon has distinct uses, the right or proximal segment being responsible for absorption and the left or distal portion for the accumulation of faeces, and that from a pathological point of view there may be right-sided or left-sided diarrhoea or constipation; in stasis of the contents in the left colon (Hurst's dyschesia) there is a remarkable freedom from symptoms, in contrast to the definite manifestations associated with right-sided stasis. In describing Bauhin's valve at the junction of the small and large intestines, Professor Carnot refers to the muscular sphincter, described in 1902 by an anatomist of the name of Elliot Keith, thus recalling two distinguished members of the British school.

The specific infective and toxic forms of colitis, including typhoid, paratyphoid, bacillary dysentery, uraemic and mercurial colitis, are summarized by Dr. P. HAVIER, who remarks that, whereas an anti-Shiga serum is effective, no benefit can be expected from an anti-Flexner serum. In this writer's account of the various forms grouped together as cryptogenic, the condition commonly though inaccurately known as mucous colitis is described under the cumbersome if more correct name of muco-membranous colopathy, and among the numerous causes mentioned importance is attached to lesions of the female sexual organs. The treatment is discussed under the three heads of the syndrome, the etiological factors, and the painful crisis; for the constipation, which with the mucous casts and the pain constitutes the three cardinal manifestations, irritating purgatives and laxatives are held to be contraindicated and the use of enemas rarely desirable, though the Plombières treatment is approved. Recto-sigmoiditis is considered by Dr. FRIEDEL, and the surgical complications of colitis, which as compared with appendicitis rarely attract attention, are detailed by Dr. G. LARDENNOIS; they include—first, acute lesions, such as severe haemorrhage which may be successfully treated by timely caecostomy, and suppurative peri-sigmoiditis; and secondly, chronic conditions such as constipation (in connexion with which Sir Arbuthnot Lane's total colectomy is critically considered), pericolitis, and megacolon.

This concise handbook may be recommended as a clear and useful guide on this subject.

## FAR EASTERN ASSOCIATION OF TROPICAL

## MEDICINE.

## CONGRESS AT SINGAPORE.

The fifth Congress of the Far Eastern Association of Tropical Medicine was opened at Singapore on September 5th by Sir Lawrence Guillemard, Governor of the Straits Settlements.

The attendance numbered over 500, and included Government delegates from the Straits Settlements, the Malay States, Australia, British India, British North Borneo, Burma, China, Formosa, Hong-Kong, Indo-China, Japan, Malacca, the Netherlands Indies, the Philippine Islands, Sarawak, Siam, and the United States, as well as representatives of numerous universities, institutes of medical research, and officers of civil medical services. The Association was founded at Manila in 1908, and its objects, as stated in its articles of constitution, include the union of the medical profession of the Far East into one compact organization, the promotion of friendly intercourse between scientific men, and the enlightenment of public opinion in regard to the prevention of disease.

The fifth congress, under the presidency of the Hon. Dr. A. L. Hoops, Principal Civil Medical Officer of the Straits Settlements, was of exceptional interest and value, and proved its success in no small measure to the active co-operation of the Malaya Branch of the British Medical Association and its indefatigable honorary secretary, Dr. J. W. Schaff, who acted as secretary and treasurer of the congress. Nearly sixty papers were submitted, most of them dealing with tropical diseases but many also of more general interest. It is intended to publish the full transactions in two volumes before the middle of next year. In the meantime a report of the congress has been published, giving a summary of the business transacted.

## The Opium Evil.

Members of congress laid stress on the necessity of employing national and international organization, as contrasted with merely local effort, for the control of many tropical diseases. An illustration was given by Dr. Gallaway in connection with the opium habit. At present opium smokers among the Straits-born Chinese are few, and will probably be extinct in the next generation. The difficulty lies in the immigrant Chinaman, who naturally brings his habits with him and dominates the position. The local Government endeavored to reduce the use of opium by raising the price of "chandu," with the result that smoking was stopped to a great extent and chandu stock for any length of time, and that the objections arising from overmilling could be overcome by improved methods of cooking and by combining other foods with rice. In some countries, Siam for instance, a large proportion of white rice is exported, and the adoption of the proposals would, moreover, probably have the effect of raising the cost of living of the poorer classes and cause widespread discontent. Mr. W. G. Maxwell, Chief Secretary to the Government of the Federated Malay States, briefly defined the position thus: "We pay a small and gradually diminishing price in the form of berr-berr, for the widespread advantages of a cheap and abundant food supply for the people."

Dr. Sawyer, of the Commonwealth Department of Ankylostomiasis, who contributed a paper on nation-wide and international organization, referred to the advantages that were derived from the expansion of the merely local efforts to control ankylostomiasis in Northern Siam into a nation-wide campaign under the Siamese Red Cross. In further illustration he gave an account of the Australian book-worm campaign. Various local efforts had been made without any tangible results, one of which, in Northern Queensland, revealed an amount of disease sufficient to cause concern as to the future progress of the region. As a result of these revelations the Commonwealth Government, one all the Australian States came into the arrangement, together with the three large territories New Guinea, Papua, and Northern Territory. Early in 1923 the book-worm survey of the whole of Australia had been completed, and the campaign had developed from local operations into a nation-wide project. Dr. Sawyer enumerated many advantages accruing from these combined efforts. For instance, in a country such as Australia, with an area of nearly three million square miles, observations could be made under most varied conditions and compared. Thus the area investigated included tropical areas, some with an average annual rainfall of over 150 inches, others with less than 10 inches; and the rainfall was found to be the dominant factor in determining the amount and distribution of infection in the tropics and subtropics. Under the conditions found in Queensland, bookworm infection in people of European derivation was usually high if there were more than 50 inches of rain in the year, and, as a rule, almost absent with less than 40 inches. Among the aborigines, many of whom went barefoot, the infection rates were much higher than among Europeans. In the vast low-rainfall areas of the interior there was no bookworm infection in any race. With regard to treatment and prophylaxis, the important observation was made that better results were obtained when less effort was devoted to securing complete cures of all infected persons, and more emphasis placed on visiting the communities often, under a systematic scheme of permanent bookworm control, which would bring every community under some degree of treatment every year. The scheme has been in operation only a short time, but from the figures derived from the last survey, which practically included the whole population, a great reduction in the percentage of cases has been effected.

## Derr-berr: Malattia.

An important matter discussed had reference to the control of berr-berr. At the meeting held in Batavia in 1921 it was recommended to the Governments concerned to take action in this matter, and the question was thoroughly debated at the present meeting on the proposals submitted by the Philippine delegates—namely, that rice should be graded according to its P<sub>2</sub>O<sub>5</sub> content (that containing 0.5 per cent. to be called "standard rice," that containing less "supermilled rice"), that the consumption of supermilled rice should be discouraged by placing a tax upon it; and that the significance of the difference between the two grades should be impressed on the population by means of an educational campaign. These proposals received practically no support. It was objected that the P<sub>2</sub>O<sub>5</sub> content may have a P<sub>2</sub>O<sub>5</sub> content below the standard and yet be unmilled and contain a sufficiency of vitamins. It was further pointed out that serious inconvenience would arise from the fact that unmilled rice cannot be kept in stock for any length of time, and that the objections arising from overmilling could be overcome by improved methods of cooking and by combining other foods with rice. In some countries, Siam for instance, a large proportion of white rice is exported, and the adoption of the proposals would, moreover, probably have the effect of raising the cost of living of the poorer classes and cause widespread discontent. Mr. W. G. Maxwell, Chief Secretary to the Government of the Federated Malay States, briefly defined the position thus: "We pay a small and gradually diminishing price in the form of berr-berr, for the widespread advantages of a cheap and abundant food supply for the people."

The President delivered an address on the prevention of diseases in the tropics, and a considerable proportion of the available time of the congress was devoted to the question of eradication was only just beginning in spite of the fact that 100,000 lives had been saved in Malaya during the last twenty-five years; since the start of deliberate anti-malarial work in 1912, 50,000 had been saved in Singapore alone by the health officers and engineers. A great advance had taken place in the knowledge of the natural history of the various species of mosquito concerned in infection in different districts; this had led to the realization of the need for preventive treatment being directed in accordance with the habits of the species concerned; previously treatment had been rather haphazard, but different places often required different methods. Better directed drainage methods and oil treatment had resulted in very considerable financial economies, and in some places the increase in

## ON SUICIDE.

In his pamphlet on suicide,<sup>7</sup> which forms one of the supplements issued from time to time by the *Monatsschrift für Psychiatric und Neurologic*, Dr. R. WEICHENRODT, who is attached to the Frankfurt University Clinic for Psychiatry and Nervous Diseases, has collected statistics showing that there has apparently been a great increase in the number of suicides since statistical inquiries on this subject were first instituted nearly a hundred years ago. During the period 1870-1900 the number of suicides in Austria rose from 1,560 to 4,215, in Italy from 836 to 2,040, in France from 4,490 to 8,926, in England from 1,495 to 2,896, in Switzerland from 321 to 746, in Belgium from 367 to 786, in Denmark from 505 to 550, and in Spain from 112 to 118. Norway was the only country which showed a slight decrease—namely, from 128 to 117. The difference in the tendency to suicide of the various races is shown by calculating the relation of the number of suicides to the population. Thus to every million inhabitants in Denmark there were 224 suicides, in Switzerland 225, in France 222, in Germany 207, in Russia 31, and in Spain only 21. The author believes that economical causes are chiefly responsible for the apparent increased frequency of suicide. Formerly suicides were much more frequent among men than among women, the proportion of male to female in the nineteenth century being four to one. In the last thirteen years before the war, while the number of suicides among men increased by only 20 per cent., the increase among women was 70 per cent., corresponding, as he asserts, to the increase in the number of women who had taken up some profession or trade. During the war decrease in the number of suicides among men was accompanied by a steady increase among women, so that by 1918 there were 63.4 suicides among women to every 100 suicides among men.

As regards the influence of climate on the frequency of suicide, Montesquieu's statement that more persons kill themselves in the winter than in the summer is held to be disproved by statistics, which show that the number of suicides increases in the spring, reaches its acme in May and June, and sinks to its lowest level in December and January.

In discussing the relation of suicide to insanity, Dr. Weichenrodt remarks that though a certain number of suicides are of unsound mind, a study of the literature and his own observations have convinced him that the estimate of one-third is much too high, as in a large number of suicides it has not been possible to find any psychical abnormalities. In conclusion, he maintains that the best prophylaxis of suicide consists in a sound ethical education at home and at school, and that the frequency of suicide among the mentally unstable can be reduced by early psychiatric treatment.

## BACTERIOLOGY.

A *Manual of Determinative Bacteriology*<sup>8</sup> has been edited by a Committee of American Bacteriologists under the chairmanship of Dr. DAVID BERGER of Pennsylvania. Its object is to provide a key to the classification of organisms belonging to the schizomycetes. Though it is based principally on the work of the Society of American Bacteriologists published in 1917 and 1920, there are a considerable number of modifications of the scheme proposed by them, as well as the introduction of many new genera, which are put forward—we hope, at least—more in a tentative manner than with any purpose of finality. Thus, for instance, the tribe Bacteriæ, comprising the coli-typhoid organisms, is subdivided into six genera—the *Escherichia*, *Aerobacter*, *Proteus*, *Salmonella*, *Eberthella*, and *Alcaligenes*. The familiar *B. coli* is now termed *Escherichia coli*, and *B. typhosus* *Eberthella typhi*. These subdivisions have much to recommend them, but we doubt whether all of them have been sufficiently carefully thought out; whether, for example, it is wise to place lactose-fermenting, indol-producing organisms in the same genus as that to which the *B. typhosus* belongs. Further evidence of

this confusion is seen in assigning *B. murisepticus*—the causative organism of swine erysipelas—to the genus *Pasteurella*, from which it is clearly separated by morphological, cultural, fermentative, serological, and pathogenic characteristics. In spite of its numerous shortcomings, however, which are inevitable in such a subject as this, the book has much to recommend it, and any criticisms we have put forward are intended more in a constructive than in a destructive sense. There is no doubt that such a work is badly needed—not so much by those engaged in clinical bacteriology as by those who are commencing to study bacteriology as a pure and not as an applied science. Just as in botany one can with the aid of Hooker determine by examination of a flower the genus to which it belongs, so now is it possible with this *Manual* to assign an unknown bacterium to its proper genus. We congratulate the authors on their attempts to solve an extremely difficult problem; their work will go far to lift bacteriological classification from the chaos in which it is at present and to place it on a sound footing.

The book *Bacteriology*,<sup>9</sup> “a study of micro-organisms and their relation to human welfare,” appears to have had its origin from a conversation held early in 1916 between the two Drs. CONN, which led them to conclude that a work dealing with general bacteriology and its applications to all branches of science was wanted. The requirements of the medical student have been well attended to by medical bacteriologists, as is witnessed by the booksellers' list: for there are big books and little books in great number. The small group of micro-organisms capable of causing human disease are undoubtedly of great importance, but they are, after all, a very small part of that vast number of microscopic creatures without whose assistance animal life on this planet would be impossible. Human welfare depends on the benefit we derive from this larger group just as truly as human disease on the menace of the smaller pathogenic group. The book has not been written specially for medical students, but it contains several chapters on pathogenic organisms; a detailed description of individual bacteria is not given, and the subject dealt with in an elementary and general fashion. A much larger part of the book is devoted to such subjects as micro-organisms in relation to the fertility of the soil, the part played by bacteria in the dairy industry, bacteria in relation to plant diseases, and the functions of micro-organisms in the manufacture of alcoholic beverages, brewing, the manufacture of vinegar, and the treatment of fodder. Thus a very wide field is covered. The descriptions are clear and concise and eminently readable. While the authors descend from the general to the particular, their detail is not always accurate, as for instance, the remark on page 134, “There is considerable evidence that long-chain-forming streptococci in milk are pathogenic forms.” The majority of the illustrations of micro-organisms have little value and many will be apt to give an erroneous impression to readers who have never looked down a microscope. It is a pity also that the authors cannot make their minds whether to employ the Fahrenheit or centigrade temperature scale; in some places they use one or elsewhere the other. These, however, are criticisms in detail, and one need not be too punctilious about detail in a book the main object of which is to present a broad and general survey of the activities of bacteria in nature and industry.

## PLANT BIOLOGY.

MR. TANSLEY tells us in the preface to his book *Elements of Plant Biology*<sup>10</sup> that it is primarily intended for students of medical and other, who must obtain some knowledge of plants in relation to general biology and who have little or no groundwork upon which to build. It may be said

<sup>7</sup> *Der Selbstmord*. By Privatdozent Dr. med. R. Weichenrodt. Berlin: S. Karger, 1923. (Roy. 8vo, pp. 44.)  
<sup>8</sup> *Bergey's Manual of Determinative Bacteriology*. Baltimore: Williams and Wilkins Co. 1923. (Med. 8vo, pp. xii+442. 5/5s. 4d.)

<sup>9</sup> *Bacteriology: A Study of Micro-organisms and their Relation to Human Welfare*. By H. W. Conn, Ph.D., and J. L. Conn, Ph.D. Baltimore: Williams and Wilkins Co. 1923. (Med. 8vo, pp. 441. 4/6s. 4d. in U.S., Canada, Mexico, and Cuba; 4/5s. 4d. in other countries.)

<sup>10</sup> *Elements of Plant Biology*. By A. J. Tansley, M.A., F.R.S., University Lecturer in Botany and Examiner in Elementary Biology to the University of Cambridge. London: George Allen and Unwin, Ltd. 1919. (Cr. 8vo, pp. 410. 10s. 6d. net.)

land values, consequent on drainage, had more than covered the total expenditure, including that of subsequent development for cultivation or building purposes. Singapore gave the members of the congress a hospitable welcome, and many excursions were made into the surrounding districts for the inspection of works of sanitary interest. The visit of the congress was also made an occasion for laying the foundation stone of the new King Edward College of Medicine, the ceremony being performed by Lady Guillemard. The college, which was founded in 1905 and is therefore the youngest medical school of the empire, was originally intended to be a training centre for subordinate local practitioners, but in 1916 a complete medical course was planned and the diploma was recognized by the General Medical Council as a registrable qualification. Dr. G. H. Macalister, the Principal, referred to the fact that some one hundred and sixty licentiates of the college were in practice in Malaya and expressed the hope that, with ample accommodation, the usefulness of the college would expand in further directions. There will be ample facilities for post-graduate study and research. The next congress will probably be held in Japan in October, 1925, under the presidency of Professor S. Kitasato.

### CRIMINAL RESPONSIBILITY.

#### REPORT BY LORD JUSTICE ATKIN'S COMMITTEE.

The Committee on Insanity and Crime appointed by the Lord Chancellor in July, 1922, has now issued its report. The Committee was a purely legal and administrative body. It consisted of Lord Justice Atkin (Chairman); Sir Ernest Pollock, K.C., late Attorney-General and now Master of the Rolls; Sir Leslie Scott, K.C., late Solicitor-General, and, in succession to him, Sir Thomas Inskip, K.C.; Sir Herbert Stephen, Bt., Clerk of Assize for the Northern Circuit; Sir Richard Muir, Senior Treasury Counsel at the Central Criminal Court; Sir Archibald Bodkin, Director of Public Prosecutions; Sir Edward Troup, late Permanent Under Secretary of State, Home Office; Sir Brinley Blackwell, Assistant Secretary of State, Home Office; and Sir Edward Marshall-Hall, K.C. The terms of reference were:

"To consider and report upon what changes, if any, are desirable in the existing law, practice, and procedure relating to criminal trials in which the plea of insanity as a defence is raised, and whether any, and if so what, changes should be made in the existing law and practice in respect of cases falling within the provision of Section 2, Subsection 4, of the Criminal Lunatics Act, 1884."

By subsequent correspondence it was made clear that the inquiry to have a wide scope and to include consideration of the rules in *McNaghten's* case, which since 1843 have formulated the English law as to the criminal responsibility of persons alleged to be of unsound mind.

Two medical documents for submission to Lord Justice Atkin's Committee were issued in March last, and reproduced in these columns.<sup>1</sup> The one was a memorandum of evidence on legal responsibility for crime prepared under the authority of the Council of the British Medical Association; the other was a report drawn up by the Medical-Psychological Association of Great Britain and Ireland. The subject had engaged the attention of the British Medical Association for some years past, and in 1913 a special subcommittee of the Medical-Political Committee was appointed to consider the present state of the law in its regard to legal responsibility for crime. In due course it presented a report, which was approved by the Annual Representative Meeting in 1915, and the memorandum submitted to Lord Justice Atkin's Committee was based on that report. The Medical-Psychological Association's report was prepared for it by a special committee including medical superintendents of asylums, several persons now

<sup>1</sup> *Cant. 2005.* To be purchased through any bookseller or directly from H.M. Stationery Office. Price 6d. net. *British Medical Journal*, March 24th, 1923, p. 518 and p. 520.

One of the difficulties encountered by the Committee in that Association's report was that "no clue to what they regard as the test of criminal responsibility," or, again, "what it was that ought to make a person of unsound mind immune from punishment for any act he might commit in violation of the criminal law." In this connexion the Committee discusses the far-reaching effect of granting immunity to everyone who can be said to be of unsound mind when the medical conception of unsoundness of mind is considered. Of this medical conception it says:

"It is accepted by the witnesses for the British Medical Association, and, of course, by us, 'Unsoundness of mind is no longer regarded as in essence a disorder of the intellectual or cognitive faculties. The modern view is that it is something much more profoundly related to the whole organism—a morbid change in the general development. Long before a patient manifests delusions or other signs of obvious insanity he may suffer from purely subjective symptoms which are now recognized to be no less valid substitutes for the picture of what condition of mind than the more palpable and manifest signs of the fully developed disorder which may take the form of delusions, mania, melancholia, or dementia.'"

"We have thus had unequalled opportunities of becoming acquainted with the considered opinions of the most eminent representatives of the medical profession on this much debated subject. We desire to express our sense of deep obligation to the associations generally and to their individual members for their valuable assistance in this respect. Unfortunately for us the difficulties presented by criticism of the existing law from the medical side were not removed; for, as will be seen, the two reports are, on the main question, in direct opposition to one another. The British Medical Association would retain the existing law with a modification as to lack of control; the Medical-Psychological Association would sweep away the present rules and substitute other questions for the jury, which they formulate. After careful consideration we come to the conclusion that we cannot accept the recommendation of the Medical-Psychological Association. In substance we concur with the report of the British Medical Association. It seems right, however, that we should not pass away from a report presented to us with such great professional authority without stating some of the reasons for our conclusions."

In certain cases, such as that described to the Committee by Dr. Carswell, the difficulty of diagnosing the accused person's state of mind, and, when some unsoundness of mind is indicated, of establishing the non-relation of the act to the unsound state of mind, would, in the Committee's view, introduce so much uncertainty into the administration of the criminal law as to create a public danger. The Committee next addresses itself to showing that much of the medical criticism directed at the *McNaghten* rules is based upon a misapprehension:

"When once it is appreciated that the question is a legal question, and that the present law is that a person of unsound mind may be criminally responsible, the criticism based upon a supposed clash between legal and medical conceptions of insanity disappears. It is not that the law has ignorantly invaded the realm of medicine; but that medicine, with perfectly correct motives, enters the realm of law."

The Committee can find no good reason why a medical expert in giving evidence at a criminal trial should not fully develop his reasons for holding the prisoner to be of unsound mind. But having given evidence of such unsoundness of mind which determines the legal issue—namely, the question of fact which determines the legal issue—namely, the question formulated at present by the *McNaghten* rules, as to the general mental condition, as a preliminary to a wise discretion would allow all necessary expert evidence to be given by the plea.

Thus the Committee holds that the existing rule of law is sound; that a person may be of unsound mind and yet be criminally responsible. If a person intends to do a criminal act, has the capacity to know what the act is, and

once that the book admirably fulfils its purpose, and that it may be read by others with both interest and profit. The author's style is so clear and easy that even the beginner can easily understand the many technical words so terrifying to the uninitiated, the derivations of the scientific terms being given as footnotes. At the end of each chapter instructions for practical work are set forth, making the book useful to teacher and student alike.

Written from the physiological standpoint, only such anatomical details are given as are necessary to understand the functions concerned. This is as it should be. The student is but too often overloaded with a mass of purely anatomical detail, resulting first in boredom and ending ultimately in aversion, because the bearing of such details upon their ultimate studies is not only difficult to comprehend, but also very frequently as difficult to justify.

More and more are biological processes finding their applications in clinical medicine. A book such as Mr. Tansley's, by stimulating general interest, makes such applications easier to imagine. The earlier chapters give a lucid account of the elementary facts of biochemistry. In other parts the curtain is lifted sufficiently to give to the intelligent beginner a glimpse of the philosophical problems with which the science of biology teems. For example, the origin and evolution of the soma and of sex are described in a series of organisms commencing with *Chlamydomonas* and terminating with *Volvox*. This is followed by an account of the nature and significance of the differentiation of the male and female gametes.

Sufficient has been written to indicate the general scope of the book. It is obviously the work of an author having the somewhat rare ability of combining scientific knowledge with simplicity of exposition, and of looking at his subject from the points of view of both teacher and student.

### NOTES ON BOOKS.

*Life Movements in Plants*, by Sir J. C. BOSE, has been issued in three parts, and we are here concerned with the third and fourth.<sup>11</sup> The movements of plant organs under the changing forces of the environment are mostly the effects of variation of temperature, of the stimuli of contact, of gravity, and of light. The reactions are identical, whatever the nature of the stimulus, but vary with its intensity, and with the physiological condition of the tissue. In the normal state the response is by contraction, in the flaccid or subtonic condition by expansion or turgescence—a species of erection leading to reversal of the direction of movement. With a feeble stimulus an expansive reaction is induced, in contrast with the contractile effect of a moderate stimulus. In addition to actual movements, response to stimulation is evidenced, it is said, by change in the rate of growth and by electrical variation. Under a subminimal stimulus the response is electrically positive and the rate of growth is accelerated; a stimulus of moderate intensity induces, on the other hand, a negative electric variation and retardation of the rate of growth. It is stated that when a plant organ is subjected to a strong stimulus it exhibits a series of multiple responses. In the leaflets of *Biophytum* there is a long refractory period and the response is on the "all or none" principle. A single moderate stimulus gives rise to a single response, and a strong stimulus causes a series of responses. The book contains descriptions of numerous experiments; in one the leaf stalk of the nasturtium was seen when placed horizontally to begin to bend upwards in the course of a few minutes; the problem was to identify the particular group of cells whose activity induces this change, and the nature of the stimulus. Using an extremely fine pointed electrode, insulated except at the extreme tip, the author sought to ascertain the electrical condition of the leaf stalk at varying distances from its surface. With the stalk in the vertical position the galvanometer showed no reaction at whatever depth the electrode was inserted, but in the horizontal position a marked galvanometric response occurred in the layer of cells characterized by the presence of starch granules. The author correlates the development of the electro-negative condition with the displacement of the starch granules, as the vertical position was gradually changed to the horizontal. Other problems investigated were the existence of tissue-tracts analogous to nerves, the possibility of the transmission of excitations to a distance, and the effects of poisons and anaesthetics.

<sup>11</sup> *Life Movements in Plants*, by Sir Jagadis Chunder Bose, Kt. M.A., D.Sc., LL.D., F.R.S., C.S., C.E., Transactions Bose Institute, Vols. II, III and IV, 1922, 1921. London and Bombay: Longmans, Green and Co. 1923. (Demy 8vo, pp. xx + 502; 327 figures. 25s. net.)

*Applied Psychology for Nurses*,<sup>12</sup> by Dr. DONALD A. LAIRD, Assistant Professor of Psychology in the University of Wyoming, as an introduction to applied psychology is the best book which has come under our notice, and if each nurse were advised to read it before completing her training many nurses and patients would be the happier. The book is a successful attempt to select from the vast literature of psychology such facts as will be of most immediate aid to nurses in understanding their patients and themselves as organisms that act, think, and feel. It is divided into four parts and has an index. The first part is introductory; the second deals with the biological foundations of behaviour; the third considers the practical applications of the results of biological adaptations; and the fourth gives a brief account of mental hygiene especially with reference to the nation. All the parts are well written and clearly presented, with an occasional lightness that will refresh the reader. At the end of each chapter is a list of topics for discussion in the form of questions which test the reader's memory and mental agility.

Dr. LEONARD WILLIAMS has revised the text of his well known *Minor Maladies and their Treatment* for the fifth edition,<sup>13</sup> issued this autumn. The chapter on minor glandular insufficiencies has been practically rewritten, as was necessary owing to the great progress in endocrinology which has taken place in the last four or five years. The author insists on the necessity of bearing in mind the important fact of the interdependence of the glands which constitute the system. We have no doubt that the book in this new edition will continue to command the approval of the profession.

<sup>12</sup> *Applied Psychology for Nurses*. By Donald A. Laird. Philadelphia and London: J. B. Lippincott Company. 1923. (Demy 8vo, pp. ix + 25; 43 illustrations. 16s. 6d. net.)

<sup>13</sup> *Minor Maladies and their Treatment*. By Leonard Williams, M.D. Fifth edition. 1923. London: Baillière, Tindall, and Cox. (Crown 8vo, pp. xiii + 414. 7s. 6d. net.)

### MEDICAL AND SURGICAL APPLIANCES.

#### A Gas-Fire Accessory.

MANY users of gas fires place a pan of water in front of the stove in the belief that the dryness of the air which results from the burning of gas and which may cause parching of the throat and irritation of the eyes is thereby diminished. The probability is, however, that any vapour which arises from the water so placed is sucked into the fire, and does not get into the atmosphere of the room at all. A patent automatic device called the "Oxyndor" has been placed upon the market by the Yorkshire Steel Company, Limited (30, Holborn, London, E.C.), wherein the open pan of water is replaced by a more scientific but not much more elaborate contrivance. It consists of a small glass cistern placed on a saucer at the side of the fire. Projecting from the saucer is a long bar of asbestos running horizontally in front of the fire. The cistern is filled with water, and within a few minutes of the lighting of the fire a small stream of vapour issues from a diffuser at the top of a vapour column parallel with the cistern. This vapour goes out into the room and moistens the air. The room can be perfumed in this way if desired, or a deodorizer can be used. We have seen the arrangement demonstrated, and it appears to do what is claimed for it. It is applicable to electric fires, and it may find a use in sick-rooms and even in hospitals as a means of doing away with almost the only disadvantage of gas or electric heating as compared with the open coal fire.

#### St. Dunstan's Clinical Thermometer.

The purchaser of a St. Dunstan's clinical thermometer will provide himself with two sources of satisfaction. In the first place he will contribute to the support of an admirable institution. One-half of the profits from the sale of the thermometer goes to the funds of St. Dunstan's. Secondly, he will possess an extremely ingenious instrument. This method for keeping a thermometer constantly in a sterilizing solution is the invention of Dr. A. McDonnell. The case consists of a double tube, the inner tube being made of glass and the outer of metal. The lower end of the glass tube is rendered watertight by means of an indiarubber plunger which is twisted and compressed by a screw. The upper end of the tube is closed by an enlargement of the upper end of the thermometer fitted with an indiarubber band. The glass tube is disconnected for filling, and inserted up to its middle in the disinfectant solution the possessor may prefer. A finger is placed over the exposed end, and the tube withdrawn half-filled with disinfectant. A small piece of rubber tube inside the glass case receives the bulb of the thermometer and prevents contact with the case. A small nut fixes the glass case to the metal tube. It is stated that the markings on the thermometer are permanent and will not be washed off by the disinfectant, whether carbolic acid 1 in 20 or mercury perchloride 1 in 1,000. The thermometer case is no thicker, and very little longer, than an ordinary case, and is supplied with a pocket clip. Messrs. J. J. Hicks are the makers of the instrument. The price is 6s. 6d.

to know the act is one he ought not to do, he commits a crime. Whether he should be punished for it is not necessarily the same question, and the Committee prefers not to discuss penological theories. Accordingly it considers that the present rules of law for determining criminal responsibility as formulated in the rules in *McNaghten's case* are in substance sound. Upon this it adds:

"The rules as to criminal responsibility apply not only to cases of murder but to the vastly greater number of less serious offences. In these cases mental conditions can be, and are in practice, duly taken into account in awarding punishment or in deciding whether any punishment should be awarded. In the case of murder the judge is not given a discretion as to punishment; but the exercise of large powers of mitigating the legal sentence. These powers will appear later, we think it is essential to recall. But we should not leave with alarm any such excessive alteration in the legal principles of criminal responsibility as is suggested by the Medical-Psychological Association. The importance of the effect upon the trial of minor offences cannot be overestimated. Insanity is admittedly incapable of definition; its diagnosis difficult; its effect on conduct obscure. The proposed rules throw upon the prosecutor the onus of establishing that the insanity said to exist was not calculated to induce the act complained of, and in default of discharge of such onus, would compel the court to order the accused to be detained during His Majesty's pleasure. The effect must be to transfer many inmates of prisons to criminal lunatic asylums and to bring within the portals of the latter many persons who are now, without any public disadvantage, placed in the care of their relatives."

A matter not covered expressly by the *McNaghten* rules is the difficult question of loss of control caused by unmanageable mind. The memorandum of the British Medical Association recommended that a person should be held to be irresponsible if prevented by mental disease from controlling his own conduct, unless the absence of control is the direct and immediate consequence of his own default. It are cases of mental disorder where the impulse to do a criminal act recurs with increasing force until it is, in fact, uncontrollable. In practice, in such cases, the accused is found to be guilty but insane. In fact, the accused knows the nature of the act and that it is wrong; and the Committee *McNaghten* formula is not logically sufficient. The Committee thinks that it would be right that such cases should be brought expressly within the law by decision or statute; that it should be made clear that the law does recognize irresponsibility on the ground of insanity where the act is committed under an impulse which the prisoner is, by mental disease, in substance deprived of any power to resist. It has no doubt that if this matter were settled most of the criticisms from the medical point of view would disappear. The Committee discusses briefly the existing practice and procedure in criminal trials where the defence of insanity is raised. These observations are grouped under the headings "Unfitness to Plead," "Evidence," "Verdict," and "Appeal." The general effect of the views therein expressed will be found briefly stated in the summary of recommendations printed below. It will be noted, in particular, that the Committee is in favour of abolishing the present verdict of "Guilty but insane" and reverting to the more logical and more satisfactory verdict "Not guilty on the ground of insanity," this phrase being extended so as to make clear that it is not insanity that is at issue, but that a degree of insanity to which the law attaches irresponsibility.

The Committee next considers the second part of its reference—namely, whether any, and if so, what changes should be made in the existing law and practice in respect of criminal lunatics. The subsection of the Act in question deals only with the procedure for inquiring into the sanity of persons under sentence of death. Powers are conferred upon the Home Secretary by other subsections in the same Act. In discussing the existing procedure in reference to the Home Secretary's consolidated and amended by the Act of 1884. Since the Insane Prisoners Act of 1840 no prisoner under sentence of death has ever been executed as to whom a certificate of insanity has been given under the state for the time being in force, and the Committee has no doubt at all that the Home Secretary should have power to remit to asylums prisoners reasonably certified to be insane, whether under sentence of death or of imprisonment.

"It seems to us that the power in question is a necessary one for which the prisoner has been convicted."

The Committee thinks it right, however, that the power of acting upon the certificate of insanity conferred on the Secretary of State should be in terms discretionary. Facts may become known which entitle the Home Secretary to allow the law to take its course notwithstanding the certificate. But if no such circumstances exist, the present practice of exercising the discretion in only one way—remitting the prisoner to an asylum—should be continued. On this matter alone Sir Herbert Stephen disagrees with his colleagues; he thinks that the certificate of insanity should not necessarily determine the exercise of the discretion, but that the Home Secretary might properly in some cases leave for execution a prisoner rightly certified to be insane.

The Committee concludes with a testimony to the scrupulous care and devotion with which the duties of the Home Office are performed, both in regard to the maintenance of the law and the legitimate protection of the prisoner. In its opinion "to the insane person justice is done."

SUMMARY OF RECOMMENDATIONS.

- The Committee summarizes its recommendations as follows:
- "1. It should be recognized that a person charged criminally with an offence is irresponsible for his act when was by mental disease in substance deprived of any power to resist. It may require legislation to bring this rule into effect.
  - "2. Save as above, the rules in *McNaghten's case* should be maintained.
  - "3. Where a person is found to be irresponsible on the ground of insanity, the verdict should be that 'the accused did the act (or made the omission) charged, but is not guilty on the ground that he was insane so as not to be responsible,' according to law, at the time. The existing statutory provision in this respect should be amended.
  - "4. Until such amendment the verdict should always be taken and entered as guilty of the act charged, but insane so as not to be responsible, according to law, for his actions at the time.
  - "5. Accused persons should not be found on arraignment unfit to plead except on the evidence of at least two doctors, save in very clear cases.
  - "6. The present law as to appeal should not be altered, i.e., there should be no appeal on the finding of insanity, either on arraignment or after trial and, in the latter case, either as to the act or omission charged, or as to insanity.
  - "7. Provision should be made, under departmental regulations, for examination of an accused person by an expert medical adviser at the request of the prosecution, the defence, or the committing magistrate.
  - "8. Provision for a panel or panels of mental experts is unnecessary.
  - "9. It is essential that the statutory power under Section 2 (4) should be maintained.
  - "10. The procedure under the subsection is satisfactory and does not require amendment.
  - "11. The discretion of the Secretary of State should be exercised as at present."

blood sugar and of sugar in the urine to about the same level as had been reached without insulin on a diet of 1,400 calories. There was also an increase, though a smaller one, in the total acid bodies. The nitrogen balance continued positive up to as much as +5 grams a day. After the above-mentioned excess of food was given, in a further fortnight of observation, not shown on the chart, the insulin was increased and the total food was reduced to about 2,500 calories.

8. The patient's weight increased steadily; 8 lb. were put on in six weeks of treatment.

9. The blood sugar was never brought below 0.11 per cent., and no symptoms of hypoglycaemia were observed.

10. The respiratory quotient was determined several times, but in this case similar figures were obtained with and without insulin. The reflection occurs that the case might not be severe enough or the dosage of insulin large enough to produce considerable changes in the quotient; especially as no attempt was made to enable the patient to assimilate much exogenous carbohydrate.

11. The investigation showed that a suitable régime for this patient is a diet of about 2,500 calories with low carbohydrate, and 30 units of insulin daily.

12. The change in appearance and attitude to life after insulin was given was unmistakable, and was remarked by the members of the staff, who, of course, know the patient well. He grumbled sometimes, as anyone might, at having to have injections and still having to look after his diet, but was interested in his various pursuits and had a look of health and keenness.

It was advised that 20 units of insulin be given just before breakfast and 10 before the evening meal, the smaller dose being given in the evening to avoid reducing the blood sugar too much in the night. This patient when at home sometimes prefers to omit lunch and make two main meals a day, with a little tea in the afternoon. In that case it was advised that the insulin should be given in two equal doses just before the two meals.

The fasting days formerly practised were omitted, but he was advised as a safeguard to take half quantities of food on one day a week. Progress will be watched, and an occasional fast day prescribed if needed.

The following is an example of a day's diet of about 2,500 calories as taken by this patient.

Diet taken on May 26th, 1923.

It will be noticed that in most cases the weights are given in multiples of 30 grams or cubic centimetres, so that the corresponding number of ounces can be approximately calculated by dividing by 30.

### Summary.

In a detailed study of a moderately severe case of diabetes in which tolerance had been diminishing for the last three years, it was found that with the help of two daily hypodermic injections of insulin, on a measured diet, the excess of sugar in the blood, the sugar in the urine, and the acidosis could be controlled; also that the patient could take more than double the amount of food he had previously been able to take without the appearance of sugar in the urine. Regulation of diet is still needed, for if an excess of food was taken above the new and higher level of tolerance, the hyperglycaemia, glycosuria, and acidosis reappeared.

The treatment led to improvement in the nutrition, physical capacity, mental outlook, and appearance of the patient.

## THE BEHAVIOUR OF THE BLOOD SUGAR UNDER THE ACTION OF INSULIN AND OTHER AGENTS.

BY

G. S. EADIE, M.B.

(From the Departments of Physiology and Biochemistry, University of Toronto.)

In view of the failure to demonstrate any action of insulin on the oxidation of glucose *in vitro* either in presence of defibrinated blood, muscle juice, a combination of these, or pus,<sup>1</sup> it seems likely that its action is indirect. Winter and Smith<sup>2</sup> have recently published some experiments which led them to the conclusion that there is present in normal blood a kind of sugar differing from an equilibrated mixture of the  $\alpha$ ,  $\beta$  varieties in having a lower specific rotation. They fail to find any evidence of this in the blood of diabetic patients, and consider that the diminished carbohydrate metabolism of the diabetic is due to the lack of this more reactive form. It became of interest, therefore, to see if their results could be repeated and to study the effects of epinephrine and insulin. The following is a preliminary account of some of these experiments. No interpretation will be attempted.

### Method.

Both dogs and rabbits were used. The rabbits were killed by knocking on the head and bled from the carotid artery; two were used in each experiment. In the case of dogs, blood was removed, either from the heart or femoral artery. The blood so obtained (usually 100 c.cm.) was treated as described by Winter and Smith—namely, diluted with seven volumes of water and precipitated with one volume each of 10 per cent. sodium tungstate and 2/3 N. sulphuric acid. It was filtered first through coarse filter paper, then through a Whatman No. 40 or 42. It was then evaporated to dryness under reduced pressure (water pump), using a capillary to prevent bumping, the temperature of the water-bath surrounding the boiling fluid being kept between 30° and 40° C.; 100 c.cm. of 85 per cent. alcohol was then added (proportionately less when less blood was taken) and the mixture let stand for twenty minutes. It was then filtered into a smaller distillation flask, and the extraction repeated with half the volume of alcohol. This was filtered in the same way, and both filtrates were united and evaporated to dryness as before. The residue was then taken up in distilled water, filtered through a No. 50 Whatman paper, and placed in a polarimeter tube. Readings were made on successive days.

The polarimeter used was a half-shade instrument made by Schmidt and Haensch. Successive readings did not vary more than 0.04°. The average of ten readings was taken. Sodium light was used. The tubes were 1.894, 2, and 2.2 cm. in length.

The copper-reducing value was obtained by the method of Shaffer and Hartmann, using the fluid in the polarimeter tube after the completion of the experiment. Blood sugar estimations were made by the same method. The epinephrine and insulin were administered subcutaneously.

### Results.

A general table of the results is given. No experiments are omitted except those in which the polarimeter reading was impossible on account of the opacity of the solution.

(a) *Normal*.—With the rabbit three experiments were done. In one of these the rotation gradually rose to a value corresponding to the reducing power. In the others there was little or no change, but the rotation found was markedly lower than that calculated from the reduction. With the

the solutions for the polariscope may be responsible for the production of substances with a lower rotating power. The slowness of the change in rotating power (intervals of days), also, does not suggest the presence of a highly reactive substance. Further investigation will therefore be necessary before the important hypothesis suggested by Winter and Smith can be considered as established. —

## NATIONAL MILK CONFERENCE.

## DISCUSSION ON PASTEURIZATION.

A NATIONAL MILK Conference, called together by the National Clean Milk Society, and supported by about thirty organizations, including the British Medical Association, was held at the London Guildhall on November 21st. Representatives were present from seventy-five local authorities and from forty-five bodies interested in public health or in dairy farming. The Conference was devoted to the single subject of pasteurization. In the morning Mr. WILFRED BUCKLEY presided (in the absence of Viscount Astor), and in the afternoon LORD DAWSON OF PENN.

Mr. RICHARD SELIGMAN opened the Conference with an exhaustive description of the methods and processes of pasteurization. He said that although great progress had been made in the details of procedure it was not possible to point to any advance in the principles of milk preservation since the days of Louis Pasteur himself. He believed that the electrical treatment of milk held promise for the future, but it needed further development before it became a commercial process. Mr. A. T. MATTICK dealt with the effects of pasteurization on the cream line. His opinion was that a smaller volume of cream might be expected to appear on milk after pasteurization by ordinary methods, though if the temperature did not exceed 145° F., and the time of exposure was not more than 30 minutes, there should be an increase rather than a diminution of the cream layer. Flash pasteurization at high temperatures would diminish the cream. A third communication was by Professor S. B. SCHUYNER, who dealt with the chemical changes produced in milk by pasteurization. He thought it improbable that either the fats or carbohydrates underwent any change during the process; the proteins, on the other hand, might be definitely altered. The lactalbumin could readily undergo coagulation and be converted into an insoluble product. The calcium and phosphate contents of milk were in the process of heating rendered more or less insoluble, and in this condition were likely to be lost.

## The Bacteriological Aspect.

Professor J. M. BEATTIE dealt with the subject on its bacteriological side. He gave an account of eight experiments, all of which led him to the conclusion that the pasteurization of milk as practised commercially in this country was not likely to destroy the common disease-producing bacteria, and in the case of bacteria more resistant to heat the process must be even more ineffective. He attached far greater importance to the destruction of the tubercle bacillus than to that of organisms of the colon type, and it was generally agreed that it was more difficult to destroy *B. tuberculosis* in milk than to destroy *B. coli*. He believed, however, that pasteurization carried out at a standard temperature somewhat higher than at present in use,\* say about 70° C. (158° F.), would bring about destruction, not only of the tubercle bacillus, but of all other important disease-producing organisms. Such a plant must be under skilled supervision, any variation of temperature must be instantly observed, and no portion of the milk must be allowed to escape exposure to the required temperature for at least 30 minutes. The present methods fell far short of establishing these conditions, with the result that pasteurized milk as commercially produced in this country was, so far as his studies went, an infective milk. An electrical method of sterilization developed in Liverpool gave constant and effective results; 99 per cent. of the total bacteria were destroyed, including all the *B. coli*, and, in every one of the experiments which he and Dr. Lewis had carried out, the *B. tuberculosis* as well.

## Effect of Pasteurization on Vitamins.

Professor F. G. HOPKINS spoke on biochemical changes. The milk constituents which at present could not be isolated by ordinary chemical means were the ferments or enzymes, certain factors concerned in immunity, and the vitamins. The enzymes of milk were either present in amounts too

small to be significant, or possessed such properties as suggested that they had no physiological function in the food, and the fact that they were destroyed in pasteurization was therefore without importance. The presence or absence of immunity factors was a matter scarcely germane to the present discussion. Vitamins called for more attention. Milk contained all the three (or four) known vitamins. In the case of two of them at least—Vitamin A and Vitamin C—the supply was minimal. When a food contained a minimum of these factors special importance must be attached to the balance which existed among them. He believed that in milk yielded by well fed cows the balance was somewhat nicely adjusted. A treatment of milk which tended to diminish the amount of any one of them was therefore, *ipso facto*, undesirable, but except in the case of one vitamin—namely, the antiscorbutic factor or Vitamin C—the assumption that pasteurization must inevitably destroy the vitamin was by no means justified. Pasteurization affected Vitamin B but little; Vitamin A, if protected from air, was also resistant to heat. A careful method of pasteurization, therefore, could be carried out without any appreciable destruction of either of these two. It was otherwise in the case of Vitamin C, but even in this case recently ascertained facts showed that there was greater stability than had been thought. If the public could be educated to understand that when an infant was fed on pasteurized milk it must be protected by the systematic administration of small quantities of fresh fruit juice or its equivalent there was, at any rate from this standpoint, no danger to be feared. He himself had never found any evidence of deterioration in general nutritive value (apart from this antiscorbutic factor) when milk was pasteurized or boiled, and Park and Holt in New York had found among infants fed on pasteurized milk, not only greater freedom from summer diarrhoea, but also a larger gain in weight, than among infants receiving raw milk.

The financial and commercial aspects of the question were treated by Mr. J. H. MAGGS (chairman of United Dairies, Limited), who said that if the public would realize that properly pasteurized milk when put into sterile bottles would easily remain sweet, if kept in the bottle in a cool place, for twenty-four hours after delivery, it would be possible to make one delivery a day the general practice, thereby reducing the necessarily greater expense (borne by the consumer) attached to pasteurization and bottle distribution.

## General Discussion.

LORD DAWSON OF PENN, who presided over the latter part of the Conference, said that it was a matter for regret that the consumption of milk per head of population in this country was so small. It worked out at only one quarter of a pint a day, whereas in the United States the average individual consumption was at least three times as large. If the smallness of milk consumption was due to a want of appreciation on the part of the people as to the value of milk, this could be cured by education, but the problem of producing milk of proper standard quality at such a price as would be profitable to the producer and not too expensive to the consumer was more difficult. Just how far a compromise could be effected was a matter for the authorities, guided by scientific opinion.

In the course of some general discussion, Dr. ERIC PRITCHARD said that the breakdown of the "cream line" did not seem to him an argument against pasteurization. After all, the agitation to which milk was subjected on pasteurization was as nothing to the agitation it underwent once it entered the stomach. The same consideration applied to the breaking down of the chemical affinities of milk. He believed that heating did not induce changes in milk of any material importance from the point of view of the consumer. Captain S. R. DOUGLAS shared Professor Beattie's view that the ordinary degree of heating in the process of pasteurization was not enough to effect the object of rendering the milk perfectly safe. Dr. W. G. SAVAGE (M.O.H. Somerset) considered pasteurization to be in itself a confession of failure; it meant that the ordinary milk supply must be regarded as necessarily dirty. He favoured a stricter control in dairying. Some procedures which were perfect on

\* The range of temperature commonly employed in pasteurization is between 140° and 150° F.

paper proved in practice to be quite the reverse. Dr. STENHOUSE WILLIAMS, of the National Institute for Research in Dairying, urged the need for care in the training of employees, and pointed out that such need would still exist even if pasteurization were generally adopted, and might even become greater. Dr. HARRIETTE CHICK urged the necessity for seeing that milk received only a single pasteurization. Professor H. R. KENWOOD said that the voluminous literature dealing with this subject on the experimental side was most conflicting. The word "pasteurization" was used in different senses by different individuals, and therefore the facts published were not comparable and led to divergent conclusions. No doubt there were also enormous differences in the methods of pasteurization employed, and in the past there had been a good deal of inefficient pasteurization. But he was convinced that the milk supply in this country was getting cleaner every year, and he did not agree that pasteurization would prejudice its continuing improvement. Dr. S. G. MOORE (M.O.H. Huddersfield) felt that the objections to pasteurization were of little weight as compared with the pronouncements of great authorities in its favour. Pasteurization was not a confession of failure, but the recognition of inexorable facts.

The constitution of the Conference did not admit of any resolutions being usefully submitted, but the general impression of those who summed up the day's discussions was that more knowledge is needed as to what actually does take place during the process of pasteurization.

### THE GENERAL ELECTION.

The following is a list of medical candidates at the General Election and of the constituencies in which they are offering themselves so far as we have been able to ascertain. An asterisk indicates that the candidate represented the constituency in the Parliament just dissolved.

- Dr. H. B. Bates (U.), Newton, Lancs.
- Dr. Ethel Bentham (Lab.), Islington East.
- \*Sir George A. Berry (U.), Scottish Universities (returned unopposed).
- Dr. W. A. Chapple (L.), Dumfries.
- Dr. R. Dunstan (Lab.), Ladywood, Birmingham.
- Dr. W. E. Elliot (U.), Lanark.
- Dr. F. E. Fremantle (U.), St. Albans.
- Dr. O. Gleeson (Lab.), Portsmouth North.
- Dr. L. Haden Guest (Lab.), Southwark North.
- Mr. Somerville Hastings (Lab.), Reading.
- Dr. G. B. Hillman (U.), Normanton, Yorkshire.
- Dr. J. E. Molson (U.), Gainsborough.
- Dr. H. B. Morgan (Lab.), Camberwell North-West.
- Dr. A. G. Newell (L.), South Tottenham.
- Lieut.-Colonel A. C. Osburn, D.S.O. (Lab.), Walsall.
- Dr. R. L. Ridge (L.), Enfield.
- \*Sir Sydney Russell-Wells, M.D. (U.), University of London.
- Dr. A. Salter (Lab.), Bermondsey West.
- Dr. R. W. Simpson (L.), Newcastle-upon-Tyne North.
- Professor Thomas Sinclair, M.D., R.U.I., F.R.C.S. (U.), Queen's University, Belfast (returned unopposed).
- Dr. G. E. Spero (L.), Stoke Newington.
- Dr. T. Watts (U.), Withington.
- Dr. J. H. Williams (Lab.), Llanelly.
- Lieut.-Colonel T. S. Beauchamp Williams (Lab.), Lambeth, Kennington.
- Dr. R. M. Wilson (L.), Saffron Walden.

Sir Henry Craik, K.C.B., has been re-elected unopposed as one of the representatives of the Scottish Universities. A further note on the medical candidates appears in this week's SUPPLEMENT.

THE Great Western Railway has printed a small handbook on spas and inland resorts on its system. Particulars are given of Bath, Cheltenham, Church Stretton, Droitwich, Leamington, and Malvern; Torquay also is described and Weymouth, where the Nottingham spa waters have again been made available. The spas of Central Wales from Bwlth to Llanwrtyd are mentioned, and there are many illustrations.

## England and Wales.

### OPENING OF NEWCASTLE MATERNITY HOSPITAL.

THE official opening by H.R.H. Princess Mary, Viscountess Lascelles, of the Newcastle-on-Tyne Maternity Hospital, took place on Saturday afternoon, November 24th. Her Royal Highness was received at the hospital gate by Lord and Lady Armstrong and the matron, and after hearing an address by the Duke of Northumberland declared the hospital open for the reception of patients. Dr. R. P. Ranken Lyle (honorary consulting obstetrician) then asked Lord Armstrong, as president of the institution, to accept a portrait of Sir James Y. Simpson, which was unveiled by Princess Mary, and Sir Thomas Oliver (honorary consulting physician) proposed a vote of thanks to the Duke of Northumberland for presiding. The various wards and other departments of the hospital were inspected and afterwards a nurses' carnival was held. The souvenir programme gives a concise account of the history of the institution and of the new building, from the pen of Dr. Ranken Lyle. The maternity hospital was founded by Act of Parliament on October 1st, 1760, in Rosemary Lane, where it was carried on for sixty-five years as an in-patient hospital, admitting on an average fifty patients a year. In 1819 a donation by Dr. Thomas Elliot formed the nucleus of a fund which enabled the governors to erect the building in New Bridge Street opened in 1826. An existing charity for attending patients in their own homes was amalgamated some years later with the maternity hospital and the name of the institution was altered to "The Lying-in Hospital and Out-Door Charity for Poor Married Women." Last year the number of indoor patients was 1,156, and 1,170 patients were attended at their own homes; the nursing staff numbered 36. By that time the accommodation had become quite inadequate for the number of patients seeking treatment, and the committee of management approached the Newcastle Corporation, which purchased the industrial schools site in City Road, and gave a portion of this land for a period of thirty years to the trustees. Reconstruction of portions of these buildings began last March and the institution was transferred from New Bridge Street to Jubilee Road in September. The present hospital consists of buildings surrounding three sides of a large quadrangle, with land available for future extensions. The site is centrally placed among the homes of the patients, and when the reconstruction work is finished the present buildings will provide a maternity hospital containing 90 beds for patients, 40 bedrooms for nurses, and ample accommodation for the domestic staff. There are separate quarters for the resident medical officers and students, and a large lecture hall. When finished the institution will be the largest maternity hospital in Great Britain. It consists of a series of units, compactly arranged. The maternity portion and the out-patient and pre-maternity departments are placed on the ground floor.

### SMALL-POX PREVALENCE.

The Registrar-General's Return of Births and Deaths in England and Wales for the third quarter of the year has recently been issued. It shows for boroughs, urban and rural districts with populations over 10,000, and port sanitary districts, the number of cases of small-pox notified in the thirteen weeks ended September 29th. The total was 662. In the first half of the year the total was 1,225, so that instead of diminution there has been a tendency towards increase. In the whole of 1922 the cases were 973, so that with three months still to go, that figure has already been nearly doubled. And 1922 itself had a much greater number of cases than the immediately preceding five years. In 1917 there were only 7 notifications; in 1918, 63; in 1919, 311; in 1920, 280; and in 1921, 336. Reverting to the cases in the third quarter of the present year, the London administrative area had 11 cases; Derby 45; Durham 4; Gloucester county borough 355, the rest of Gloucestershire 43; Middlesex 5; Nottingham 121, of which 56 were in Kirkby-in-Ashfield Urban District, and 37 in Warsop Urban District; the North Riding of Yorkshire 11, all in Middlesbrough; the

## Medicine.

L. ORNICHTIA (Arch. de med., cir. y esp., September 29th, 1923, 577) states that gall stones

[illegible][illegible]

on milk diet, kept in bed, and given bismuth morning and evening in 5 g. doses. If there be an ulcer present, the pain is rapidly relieved, but little or no effect occurs in cholelithiasis. According to Roger Claudon diarrhoea is almost always ineffective in gastric ulcer, whereas it relieves the pain due to gall stones. The Gerbard physicians regard the prognosis of cholelithiasis as very favourable. Ritter has not seen a death among 4,000 cases and has had operations performed on only 3. On the other hand, Binder states that the mortality in private practice is 11 per cent. and in hospital 13 per cent.; Hirschberg estimates the mortality at 6.93 per cent. and Klinge at 3.16 per cent.

[illegible]

The oesophagus and the pus is vomited up. It may also capture into the trachea or a main bronchus and the pus is coughed up. Posterior mediastinal pleurisy, of which Polak's pleurisy is an example, is the rarest form of mediastinal pleurisy. It may give rise to the following symptoms by pressure on various organs in the posterior mediastinum—difficultly in swallowing, hoarseness, venous obstruction by pressure on the large veins, and a paroxysmal cough through pressure on the vagus. An area of impaired resonance close to the vertebral column has been described by Dienthal and was present in Polak's case in the form of a right-angled triangle.

383. Sydenham's Chorea and Lethargic Encephalitis. L. BABOSKEIX (*Paris med.*, 1923, p. 255) discusses the question as to whether Sydenham's chorea is an independent disease or only a manifestation of lethargic encephalitis. There are, undoubtedly, close resemblances between the two conditions, alike from the clinical, anatomical, biological, and nosological standpoints. Baboskeix, however, is of opinion that certain forms of acute chorea in childhood are also jointly independent of lethargic encephalitis, their characteristic features being as follows: "They appear only in a sporadic form, are preceded by articu-

[illegible]

334. Tuberculosis of the Mesenteric Glands.

F. LÖTSCH (Klinische Wochenschrift, October 8th, 1935, p. 1332) describes the enormous increase of tuberculosis in Germany since the beginning of the war. In childhood 20 to 25 per cent. of the tuberculosis arises from the intestinal tract (the infection being from both human and bovine types of the tubercle bacilli). According to Ryle's estimates 4 million children in Germany suffer from tuberculosis; of these 1 million from alimentary tuberculosis affections, including 400,000 from bovine tuberculosis infection. Since the war bovine tuberculosis has increased enormously. The infection of children is caused by bad milk and butter, insufficient sterilization of milk, greater consumption of unboiled milk, less careful inspection of meat, and diminished resistance of the body through deficient food. Isolated tuberculosis of the cervical and of the bronchial lymphatic glands is well known. Isolated tuberculosis of the intestinal and mesenteric glands also occurs. Complications are rare and some generalized glandular affections, calcification, and atrophy of the glands, defective nutrition, and absorption, isolated wasting (hence the name of the mesenteric glands usually ends in tuberculosis of the mesenteric glands) are not infrequently associated with the disease. The course is chronic, but acute complications arise. The chief symptoms are abdominal pain and tenderness at the umbilicus or to the right iliac fossa (but not the miliary miliary nodules) and wasting and subfebrile temperature; sometimes enlarged glands are felt in the right lower abdominal quadrant. Calcareous glands may be recognized by the x rays. When the disease is advanced the milk and butter should be examined for bovine tubercle bacilli. Unboiled milk should be forbidden. The risks from open tuberculosis in another member of the family should not be forgotten. Open-air treatment, sunshine, and good food are of the greatest value. Surgical treatment may be required for complications. The removal of the enlarged glands may be considered if other treatment fails.

385. **Intrapertoneal Infection of Antioxin in**  
H. S. ELIOT (*Arch. of Ped., September, 1923, p. 570*) states that a method not previously employed for the administration of antioxin in diphtheria, but commonly used in the giving of fluids, and more recently still of whole blood, to infants is the intraperitoneal route. The absorption power of the peritoneum, previously shown by many observers, suggested this area as a possible route for antioxin. The antioxin is introduced through the linea alba just below the umbilicus, the skin is pierced with iodine and alcohol, and the area may be rendered anaesthetic by ethyl chloride. The antioxin is introduced by gravity from an infusion bottle in doses of 10,000 to 14,000 units with 8 to 10 c.c. of saline. The skin and subcutaneous tissues are picked up by the thumb and index finger, and the needle is inserted obliquely, pointing upward. Flairon has used the intraperitoneal method in 12 cases in patients aged from 5 months to 10 years; 10 recovered without complications, and 2 who were almost moribund on admission, died, death being due in one to laryngeal diphtheria and extensive pneumonia, and in the other to septic diphtheria and haemorrhagic myocarditis. In both cases the peritoneum

West Riding 53, of which 28 were in Doncaster Rural District, and 17 in Bentley with Arksey; Monmouth 5; Surrey 2, and Wilts 2. The following areas had one case each: Buckingham, Lancaster, Oxford, Somerset, and Warwick.

#### TREATMENT OF LONDON SCHOOL CHILDREN.

The London County Council is making provision for the treatment at elementary schools and among certain pupils at the secondary schools during the year 1924-25 of 34,440 eye cases, 13,250 ear, nose, and throat cases, 2,210 cases of ringworm, 63,580 minor ailment cases, and 117,810 dental cases. The only considerable increase is in the provision for minor ailment and dental cases. The cost is estimated at £86,740, an increase of about £900 on the expenditure for the current year. It is proposed that the present fees of the medical and dental staffs shall be retained. "The character of the work done," the report of the Education Committee states, "requires that practitioners with specialist qualifications should be appointed to the clinical posts at the treatment centres, and it is now made a condition that all officers appointed should have had such experience. If the rates of payment were reduced we feel it would be impossible to obtain the services of such persons. At present the standard of treatment is a high one, and we are of opinion that it should be fully maintained." For doctors the remuneration is at the rate of £80 a year for service at one session of two and a half hours' duration a week, for anaesthetists £75, and for dentists £60. In certain departments the session is of two hours' duration only, and here the remuneration paid to the doctors is at the rate of £66 a year.

#### ROYAL DENTAL HOSPITAL, LONDON.

The annual dinner of the staff and past and present students of the Royal Dental Hospital of London was held on November 24th, when Mr. G. Northcroft, O.B.E., presided over a company of two hundred. Among the guests were Sir Humphry Rolleston, Sir William Willcox, Miss Aldrich-Blake, and the deans of several of the London hospital medical schools. After the toast of "Our Most Illustrious Doctor, His Majesty the King"—the form in which the loyal toast is now ordained to be given in the schools of the London University—the chairman proposed the health of the past and present students. At the same time he demurred to the title "past students," because the best members of the dental profession as of the medical remained present students all their lives. He mentioned several recent developments at the hospital and school, including the provision of a research department, certain new scholarships, and increased facilities for post-graduate study. He also announced, evidently to the great satisfaction of the present students, that playing fields had just been acquired at Golders Green. Mr. G. G. Campion, President of the British Dental Association, in responding to the toast, said that he looked forward to the better and more systematic provision of post-graduate teaching in London. He thought that a "constellation of associations" could be formed from the present dental schools together with practitioners who had distinguished themselves in the various branches of the profession so as to permit of the organization at certain hospitals in rotation of courses of post-graduate teaching, each course to extend over one or two months. One of the students, Mr. F. G. Alford, the winner of the Saunders scholarship, also responded to the toast in a happy speech, in which he took occasion to deal faithfully with the examiners and the teaching staff. The dean of the school (Mr. H. Stobie) reported a very satisfactory state of affairs, with 353 students on the books (of whom 49 were women), 68 new entrants during the year, and 85 successful students out of 111 in the final examination for the L.D.S. A lectureship in radiology had been instituted, and many post-graduate lectures had been given, with an average attendance at each lecture of 150. He reported the resignations of Sir Frank Colyer and Mr. W. H. Dolamore, the former after thirty-three years on the staff (forty-six altogether in connexion with the hospital), and the latter after thirty-one. Both had done a great work for the school; Sir Frank Colyer was one of the finest teachers it ever had, while Mr. Dolamore was responsible to a great extent for the inclusion of the school in the University of London. Mr. B.

Grellier, M.C., proposed the health of the visitors, a toast which was responded to by Professor W. Wright, dean of the London Hospital medical school, who appeared as spokesman for a "friendly tribe," and a successful evening came to an end with compliments to the chairman.

## Scotland.

#### RESEARCH ON ANIMAL BREEDING.

THE third annual report of the Edinburgh University and the East of Scotland College of Agriculture Joint Committee on Research in Animal Breeding contains interesting results of the past year's research. The joint committee, under the chairmanship of Professor Sir Edward Sharpey Schafer, consists of representatives of the University of Edinburgh, the Royal (Dick) Veterinary College, and the agricultural interest. The director of the Animal Breeding Research Department, which was set up by the committee in February, 1921, at High School Yards, Edinburgh, is F. A. E. Crew, M.D., D.Sc., Ph.D. It is hoped that the agricultural community will recognize that the future of this institution lies largely with it. Reprints of published papers will be sent on request to persons interested, and working accommodation will be provided for anyone who wishes to undertake a piece of approved research. It is intended to build up a "clearing-house" of experience in which animal breeding records will be filed so that full information may be available in response to relevant inquiries. At a later stage it is hoped to obtain an institutional farm, where more special investigations can be conducted. In addition to research work and lecturing in the University, workers have read papers before various societies interested in biological and agricultural subjects in different parts of Scotland and England. An investigation into the pathology of the "bulldog-calf" of the Dexter breed of cattle has been completed. After two years' work the condition is found to be closely allied to achondroplasia in human beings. There is a condition of abnormal endochondral ossification, the adrenal and thyroid glands are defective, and the course of events is such as would follow removal of the anterior lobe of the pituitary. Suggestions are made to breeders for avoiding the occurrence of this monstrous calf. Several pieces of research on the problem of intersexuality in domesticated mammals and in fowls have been carried out. A large number of old hens showed gradual assumption of the male secondary sexual characters. One bird having functioned for three years as a female ultimately assumed male plumage and became the father of chickens. A very extensive experiment on the subject of inheritance of characteristics which distinguish the various breeds of domestic fowl is being carried out on several hundred fowls of different breeds. Other lines of research which are being pushed forward include experiments as to the part played by the ductless glands in regulating growth and sexual maturity; studies on the histology of the sexual glands of fowls, especially with regard to the question of sex reversal; and studies on the factors involved in incubation, in connexion with which the curious point has been noted that the temperature of the naturally incubating egg is considerably higher than that of the surrounding air. An attempt is being made by microscopical study of fleeces to translate the various grades of "kempiness" in the adult fleece into definite figures which will prove a basis for further genetical work.

#### SOCIAL SERVICE WORK AT THE ROYAL INFIRMARY, EDINBURGH.

The Edinburgh University Settlement (School of Social Study) has for over seven months carried on a scheme of social service work in connexion with the out-patient department of the Royal Infirmary. It has been recognized by the managers. A report covering this period of organization has just been issued. Over 300 cases have been investigated; the work has consisted in following up needy cases in their own homes, providing the necessary means, if such are not forthcoming, for the treatment prescribed, whether it be medicine, nourishment, convalescent homes, or the readjustment of home conditions from a health point of view. The

Actual Caution.

[illegible]

Appendix Statistics.

states that from 1919 to 1922 inclusive 203 cases of appendicitis were treated in the municipal hospital at Wolden. All but 7, in whom the symptoms were very mild, underwent operation. A classification of the remaining 202 cases according to the date of operation, gave the following results: 36 were operated on on the first 10 days of the epidemic, or a total mortality of 1.5 per cent; 105 patients, or a total mortality of 1.9 per cent, were operated on during the second 10-day non epidemic interval; and 61 patients, or a total mortality of 1.5 per cent, were operated on during the last 10 days of the epidemic.

Mobilization of Ankylosed Joints.

however, were not due to appendicitis or the operation, but to pre-existing disease—namely, cerebral influenza in one case and pneumonia in the other. Fifty-eight were operated on between the third and fifth days, with 7 deaths, or a mortality of 12 per cent.; and 42 cases later, with 7 deaths, or a mortality of 16.6 per cent. The total mortality, therefore, was 7.8 per cent. The causes of death were as follows: 9 per cent., cerebral failure, 3 cases; pneumonia; embolism, pneumonia, encysted abscess, erosion of the iliac artery, and abscess in Douglas's pouch with secondary perforation, 1 case each. Peritonitis occurred in 15 cases, with 9 deaths, or a mortality of 60 per cent. Appendicular abscesses were present in 43 cases, with 3 deaths, or a mortality of 7 per cent. Of the 209 patients, 110 were males and 99 females. The mortality was aged from 10 to 30. The operative method chosen was the oblique incision 7 to 8 cm. long. Healing took place by first intention in all cases without any hernia formation. The complications noted were as follows: pyosalpinx, 2 cases; cystitis, 2 cases; prostatic abscess, 1 case; pneumonia, 1 case; erosion of iliac artery, and pulmonary tuberculosis, 1 case each.

1. The first of these is the fact that the

ACCORDING TO F. HIXMAN, J. E. GIBSON, AND A. KUTZMANN  
(Surg., Gynecol., and Obstet., October, 1923, p. 429), it is  
undoubtedly, in cases in which there is reasonable suspicion  
that a testicular tumor may be malignant, to expose it  
by operation, followed by simple castration and immediate  
microscopical examination; if indicated by the histological  
findings, radical operation will exist without delay.  
As regards glands of the testis, lying retroperitoneally along the  
aorta and vena cava in the loin, should then be done,  
humanistic and massive testicular tuberculosis, the authors  
advice which is likely to be curable, and the only testicular  
tumor which requires treatment.

In summary, it is better to operate unnecessarily in an occasional  
case than to lose the chance of cure in a case which is radically  
curable. From an anatomical point of view, the glands are personal-  
ly of radical operation, or of which 10 are personal-  
ly 73 cases of radical operation, or of which 10 are personal-  
ly 20 per cent. of cases of malignant disease of the testis,  
the presence of palpable intratesticular contractions had a  
radical operation, which in 9 such cases of the series had a  
mortality of 10 per cent.) and points rather to radium and  
x-ray therapy, which has occasionally had brilliant successes.  
In cases where there was an operation to have incomplete  
removal, not previously, but previously, in  
cases related radically to metastases were found by  
microscopical examination of the lumbar glands removed;  
in 8 of the 26 cases in which the lumbar glands removed  
metastases. Of 26 cases in which the lumbar glands removed  
demonstrated microscopically demonstrable metastases, 17 are  
living (for four years), and of the 25 in which the glands did  
not appear to contain metastases 12 are living (for over  
one year). The conclusion is drawn that radical operation  
improves the prognosis by at least 100 per cent. Clinically,  
however, there is no sign or symptom that is  
characteristic of malignant disease of the testis; a smooth  
glular surface is the rule, the tumor appears in most  
cases to be of uniform hardness; the spermatic cord may be

funds of the University Settlement are used as far as they will go, but reliance is chiefly placed on help obtained from existing charities and other agencies; their resources are co-ordinated and cases requiring assistance are brought to their notice by the social workers. Among these agencies, the report mentions seven convalescent homes, six church organizations, three army associations, and eleven other charities of various kinds. In addition to these the social workers have obtained the co-operation of open-air schools, special schools, boy scouts, girl guides, clergymen, landlords, and employers. A special denture fund has been started to which people may contribute by weekly instalments; the Dental Hospital has arranged to give to patients utilizing this scheme the privilege of obtaining dentures 25 per cent. below the usual cost. Careful card records of cases are kept and if the cases are admitted to hospital the cards are passed on to the Samaritan Society, which does similar social work for in-patients.

#### CENTRAL MIDWIVES BOARD FOR SCOTLAND.

At the recent examination of the Central Midwives Board for Scotland, held simultaneously in Edinburgh, Glasgow, Dundee, and Aberdeen, 134 candidates appeared. Of this number, 124 were successful. Of the successful candidates 29 were trained at the Royal Maternity Hospital, Edinburgh, 57 at the Royal Maternity Hospital, Glasgow, 6 at the Maternity Hospital, Aberdeen, 10 at the Maternity Hospital, Dundee, 8 at the Queen Victoria Jubilee Institute, Edinburgh, 6 at the Cottage Nurses' Training Home, Govan, Glasgow, and the remainder at various recognized institutions.

At a special meeting of the Board held for the hearing of penal cases, Dr. James Haig Ferguson in the chair, a certified midwife was cited to appear for having been in attendance upon a patient suffering from puerperal fever and failing to notify the Local Supervising Authority thereof, and to take and record the pulse and temperature of the patient, and for other breaches of the rules. The Assistant Medical Officer to the district was present in support of the charges. The Board found the charges proved and instructed the secretary to remove her name from the roll and to cancel her certificate, and, further, to prohibit her from attending women in childbirth in any other capacity. At the same meeting a number of other cases of minor breaches of the rules by midwifery nurses were under consideration and it was resolved to issue warning notices in the circumstances.

#### ABERDEEN MEDICO-CHIRURGICAL SOCIETY.

The annual business meeting of the Aberdeen Medico-Chirurgical Society was held on November 22nd, when the following office-bearers were appointed for the ensuing session: *President*, Dr. George M. Duncan; *Vice-President*, Dr. Peter Howie; *Secretary*, Dr. H. Edgar Smith; *Recording Secretary*, Dr. H. Ross Souper; *Assistant Secretary*, Dr. Robert Richards; *Treasurer*, Dr. George Rose; *Librarian*, Dr. W. Clark Souter; *Editor of Transactions*, Mr. G. H. Colt; *Members of Council*, Dr. Alexander Ogston, Dr. James Crombie, Dr. W. Clark Souter, Dr. William Brown.

## Ireland.

#### REPRESENTATION OF QUEEN'S UNIVERSITY, BELFAST, IN THE IMPERIAL PARLIAMENT.

SIR WILLIAM WHITLEA, M.D., intimated lately that he would not seek re-election as representative of the Queen's University, Belfast, in the Imperial Parliament. At a meeting of the Unionist Association of the graduates held in Belfast on November 22nd, when Professor Lindsay, M.D., was in the chair, a resolution was passed by acclamation, conveying to Sir William Whitlea the warmest thanks of the Association for the admirable way in which he had discharged his duties as their parliamentary representative. It was then unanimously decided on the motion of

Dr. Leslie, seconded by Dr. R. Henry, to accept the recommendation of the Central Committee that Professor Thomas Sinclair, C.B., F.R.C.S., Colonel A.M.S., should be selected as candidate. Mr. Sinclair, in expressing his acknowledgements, said that as a professor in the College for thirty-seven years and as deputy vice-chancellor of the University he had acquired a sound knowledge of what the University wanted in all the faculties. It would be his earnest endeavour to investigate all educational proposals which might be made in the Imperial Parliament and support those which seemed to be good. Mr. Sinclair has been elected unopposed. Professor Sinclair, who graduated at the Royal University of Ireland in 1881, became F.R.C.S. Eng. in 1886. He is surgeon to the Royal Victoria Hospital, and professor of surgery in the University. He represents the Queen's University on the General Medical Council. During the war he served with distinction as consulting surgeon with the British Forces in France, and received the honour of C.B.

#### STILLBIRTH AND NEO-NATAL DEATH.

At the third meeting of the Ulster Medical Society held in Belfast on November 15th, Dr. F. J. Browne, of Edinburgh, read a paper on stillbirth and neo-natal death. The deaths might be classified as ante-natal, intra-natal, and neo-natal. Asphyxia neonatorum was present in 50 per cent. of the intra-natal deaths. The causes were breech presentations, disproportion between head and passage, and occipito-posterior positions. He advocated conversion to normal of breech and occipito-posterior positions. He said that cerebral haemorrhage was found in 20 per cent. of all cases of stillbirth; he showed the relations of this accident to the age of the child and to tears up the tentorium cerebelli, and discussed the possible effect of these tears in producing maldevelopment of the brain, and to crime. A breech presentation was eighteen times more likely to cause a tear in the tentorium cerebelli and ten times more likely to be attended by haemorrhage; the doctor who did not convert a breech presentation might be guilty of increasing the criminal population. In discussing the influence of syphilis he referred to the curious phenomena of Colles's law, to the great rarity of a typical history of syphilis, to the great frequency with which the Wassermann reaction was negative in the mother of undoubtedly syphilitic children, and to "the lucid intervals" when a perfectly healthy child was preceded and followed by an undoubtedly syphilitic child. Passing to the observations he had made at the *post-mortem* examination of syphilitic infants, he said that spirochaetes might be found, sometimes in enormous numbers; the lungs, the thymus, the pancreas, and the uterus might all show signs. Each successive pregnancy should be treated up to the end. Mercury and arsenic should not be given to the pregnant woman together, as the kidneys were not able to stand the combination. Pneumonia was found to be the commonest cause of death of infants in the first fortnight; it was generally of the catarrhal type. Many cases of supposed overlying were really due to pneumonia; the only absolute evidence was microscopic. The necessity of ante-natal care and of regular clinics for this purpose was insisted on.

In the course of the discussion which followed, Professor Lowry expressed the hope that Dr. Browne's work would act as a stimulus to all members of the profession and would help to induce the public to establish ante-natal clinics and so bring Belfast up to the level required by modern science.

Professor Wilson advocated the establishment of a large and well equipped maternity hospital in Belfast. Dr. Thomas Houston pointed out the value of the Dreyer method of estimating a Wassermann reaction; and said it would be of great interest if cases of mothers with a negative result by Harrison's or Fleming's method could also be tested by Dreyer's method.

Dr. John Campbell, M.P., who proposed a vote of thanks to Dr. Browne for his address, said he had often wondered whether deformities might not have a syphilitic origin. Mr. R. J. Johnstone, M.P., seconded, and the vote was carried by acclamation.

## India.

## RANGOON MEDICAL SCHOOL.

The annual report for 1922-23 of the Government Medical School, Rangoon, shows that there has been a steady increase in the number of medical students. During the year fifty new students were admitted, making a total of 223, and of these thirty-one qualified and seventeen gave up their studies for various reasons, leaving 175 students on the roll at the end of the year. At the primary and intermediate examinations 75 per cent. of the candidates proved successful at the first attempt. At the final examination twenty-three out of thirty-one candidates passed at the first attempt in April, 1922, and eight were referred for six months; in the examination in October, eight of the ten who appeared were successful.

## MEDICAL INSPECTION OF STUDENTS.

The report on the medical inspection of the students of the Lucknow University in 1922-23, by Dr. Banarsi Das, medical officer, Lucknow University, states that of the 333 students who appeared for medical inspection, 252 were Hindus; 66 per cent. of them were married. Of 75 Mohammedans, 36 per cent. were married; all of the other six students were unmarried. Of the whole number 40 per cent. had defective vision, which in many instances could be corrected by glasses; four cases of trachoma were noted. Decayed teeth were observed in 47 cases; there were 9 cases of definite pyorrhoecia, and 34 of spongy gums. Half of the students habitually chewed *pan*, and this was considered to aggravate unhealthy conditions of the mouth. Apart from those who smoked occasionally, 22 per cent. smoked habitually. Almost 50 per cent. of the students were strict vegetarians and the others lived on mixed diet; only two took alcohol, and one used *bharg* on rare occasions. Practically every student had had malaria, but not one case of enlarged spleen was detected. There were about a dozen cases of ringworm, and *T. versicolor* was also observed. The average height of the students (males), who were between 19 and 25 years of age, was 5 ft. 2 in., and the weight 8 st.; it is stated for comparison that in European countries between the same ages the average height is 5 ft. 7½ in. and the weight 10 st. 6 lb.

## VACCINATION.

Some idea of the kind of organization that exists for vaccination in India may be gathered from the report for 1922-23 of Lieut.-Colonel W. M. Anderson, C.I.E., I.M.S., on the work in the North-West Frontier Province for that year. He states that the total number of vaccinations performed was 144,155, being a most satisfactory increase over the 100,219 of the preceding year. All the districts and agencies but one shared in the increase, and the average for each vaccinator was 3,837 operations, the highest figure being over 5,000. Of 108,460 successful primary vaccinations nearly two-thirds were in infants under 1 year, and the rest in children between 1 and 6 years. The rate was 40.3 per 1,000 of population against a five years' average of just under 37. The revaccinations numbered 30,188, compared with a five years' average of 17,980. Superintendents inspected a total of 100,846 cases and recorded a percentage success of 96.81 in primary vaccination and 87.56 in secondary operations. The only unsatisfactory feature appears to be, as pointed out in the report, the small number of vaccinations inspected by the civil surgeons themselves—namely, 3.67 per cent. of the total performed. In these cases the primary successes were 93.87 per cent., and in revaccinations 66.72, but Lieut.-Colonel Stiles Webb, I.M.S., who inspected 1,106 cases, reported a success ratio of 94.4, including both primary and revaccinations, so that the results tallied on the whole. The Vaccination Act is in force in only nine towns in the Province, and in Peshawar city it is still voluntary, so that a number of children remain unprotected, whilst the municipality has reduced its vaccinators from five to two. On the other hand, vaccination is gradually becoming more popular in the rural population, and resistance to primary vaccination is not offered. The result of the year's work is regarded by Lieut.-Colonel Anderson as being on the whole very satisfactory, though two superintendents had to be relieved of their duties owing

to inefficiency and slackness, and vaccinators need the stimulus of constant supervision. In the past five years the small-pox mortality was 0.37 per 1,000 of the population, and during the year under report 0.05 per 1,000. Lieut.-Colonel Anderson is to be congratulated on a very interesting report and on the good work he is doing.

## PASTEUR INSTITUTE, KASAUJI.

The report for 1922 of Major Stevenson, director of the Pasteur Institute, Kasauli, presented to the annual meeting at Simla on September 6th, showed that 6,673 persons had received the full course of vaccine treatment for rabies, 559 being Europeans and 6,114 Indians. The decrease of 331 patients as compared with the previous year was due mainly to a decrease in the number from the Indian Army. The number of patients from the Punjab, United Provinces, Central Provinces, and Central India had increased, but a decrease was noted in Bengal, Bihar and Orissa, Rajputana, and Baluchistan. In the case of 402 persons treatment was not necessary or was discontinued on information being received that the biting animal was not in an infective stage of rabies. Of those who received treatment 67, including one European, contracted the disease and died. The financial statement showed a credit balance of 9,324 rupees.

## NURSING IN INDIA.

Lady Reading has issued an appeal on behalf of the Lady Minto Nursing Association, of which she is president. The object of the Association is to enable Europeans to obtain skilled nursing at moderate charges by nurses selected in Great Britain; a sliding scale of fees is arranged, determined by the income of the patient. During 1922 the expenditure of the Central Committee of the Association amounted to nearly two lakhs of rupees, of which more than two-thirds was covered by receipts from nursing fees. A grant from the Government and interest on investments amounted to half a lakh, but the total subscriptions only amounted to 1,500 rupees.

To deal with the problem of nursing the native population in India Lady Reading has founded the Nursing Association which bears her name; it will seek to induce educated Indian women to enter the ranks of the nursing profession. Up to the present nursing in India has been monopolized almost entirely by English and Anglo-Indian nurses. In the last few years, as the *Pioneer* comments, circumstances have tended to reduce the factors which have deterred Indian women from seeking economic independence in a professional career, and Lady Reading's call is well timed. On the basis of English conditions, a minimum of 3,000 Indian nurses is required. From the report of the European Mental Hospital at Ranchi it appears that not only is there a total absence of nurses with any recognized qualification for nursing mental cases, but, according to the *Pioneer*, there seems hardly any incentive to obtain such nurses. Major Berkeley Hill, in the report, expresses the opinion that an attempt should be made to develop a body of trained nurses for mental hospital work.

## Correspondence.

## PIGMENT AND CANCER.

SIR,—I have read with much interest in your issue of November 17th the Bradshaw Lecture on melanosis by W. G. Spencer, and I regard it as an important and valuable contribution to the etiology of new growths. I feel, however, that the value of the paper will be to some extent counteracted if we accept the view put forward in your leader of November 17th, where you say that "the function of pigment in the biological world appears to be similar to its function in the industrial world: it is either decorative or protective." This restricts the use of pigment, but I consider that its field of work is of much wider extent. We are justified from facts already known in taking a much wider view of pigment as an active agent in the human economy. That it holds this position is clear from the admitted connexion between the chlorophyll of plants and the haemoglobin of the blood. The pigments of animals owe their origin in all probability to three func-

uterus may be impossible until an advanced state of pregnancy. But a sign which has enabled Keob to decide that the uterus is gravid is a change of position of the myometrium, with relation to the rest of the uterus, which the second examination shows also to have become enlarged. Two illustrative cases are given, and a third is recorded in which a myomatomous uterus removed by abdominal operation was found to contain a three months' fetus; the patient, a 7-part aged 46, had noticed enlargement of an abdominal tumor during three months, during which there had been pain and metrorrhagia. Malignant degeneration of a myoma was suspected. At operation there were found a large myomatomous uterus and a smaller one on the right, and a venous engorgement in the right broad ligament. The ovaries were not incised, but the right one was subsequently found to contain a corpus luteum of pregnancy.

397. Treatment of Eclampsia.

According to R. McDERMOTT (Boston Med. and Surg. Journ., August 16th, 1923, p. 219), death from eclampsia is practically always due to rupture of cerebral blood vessels, the chief cause being the higher blood pressure which obtains during the convulsions. It follows that the main principles of treatment should consist (1) during pre-eclamptic states, in preventing the onset of eclamptic fits, and (2) after the superposition of a definite condition of eclampsia, in preventing recurrence of the convulsions. The most constant and significant warning of an impending toxic state in pregnant women and having fits of blood pressure, next in importance among the pre-eclamptic signs, are, first, the presence of albumin, or casts in the urine, and secondly, progressive morbid lesions in the fundus oculi. Accordingly, every pregnant subject should, as a routine, receive frequently repeated examinations of the blood pressure, urine, and ophthalmoscopic findings. In the majority of pre-eclamptic cases toxæmia can be averted by increasing the amount of fluid ingested and decreasing the meat and eggs of the diet; by securing adequate elimination by the bowels, kidneys, and skin; and by securing proper exercise and an adequate amount of sleep. In the rare instances in which these measures do not produce an amelioration in the patients' condition, treatment of the pregnancy should be considered before eclamptic seizures take place, and should be done by one of the gentler measures, the use of chloroform being avoided. For the treatment of frankly eclamptic cases McDermoston has found a modification of the Rokitansky method to be followed by a considerably lower mortality, both local and maternal, than that of rapid termination of pregnancy by vaginal or abdominal hysterotomy, or by forced dilatation of the cervix and podalic version. On admission to hospital the patient, after measurement of the blood pressure and removal of the catheter, is placed in a darkened room, and quiet room, and given subcutaneous morphine and phosphate 1/2; the stomach is washed out, two ounces of castor oil being poured down the tube; and the colon is irrigated with 5 gallons of 5 per cent. glucose solution. If the systolic blood pressure is greater than 175 mm. venesection is done, so as to reduce the pressure to 150 mm. Subsequently morphine is given every hour until the convulsions drop to 8 a minute; by this time the convulsions have usually ceased and the patient has fallen into labour, which, as a rule, is terminated in a short time, normally or by a cesarean section. It is not wise to bleed a patient whose blood pressure is not greater than 175 mm. of mercury, for if during or after delivery a considerable amount of blood be lost it is possible that the blood pressure will be so greatly reduced that the patient will die of shock.

Pathology.

398. Experiments in Immunity to Tuberculosis. P. WILKINSON (Dent. Med. Assoc., September 21st, 1923, p. 1191) reviews his experience since 1920 with vaccines made from defatted tubercle bacilli and with defatted cultures of tubercle bacilli injected into experimental animals. In attempting to remove the fatty and waxy capsule of the tubercle bacillus he has used ether, chloroform, alcohol, benzol, lactic acid, carbon tetrachloride, various combinations, and he has found that only chemically pure trichlorobenzene is capable of defatting the tubercle bacillus. His experiments have, however, convinced him that immunity to tuberculosis cannot be achieved at the time by the injection of products of the tubercle bacillus.

bagging, whatever the treatment these products have been submitted to. Somewhat more encouraging results were obtained by the prophylactic treatment of cattle with injections of large and increasing doses of attenuated strains of the tubercle bacillus, and the author intends to carry out therapeutic tests with the serum of cattle thus treated. He refers to the remarkably good clinical results already obtained with such serum by Professor Czerny, who has given them to children suffering from severe pulmonary tuberculosis.

399. Reinfection of Rabbits with the Same Strain of Spirochaeta.

It has been assumed by certain authors that a rabbit cured of infection with a particular strain of spirochaeta is therefore insusceptible to reinfection with the same strain. A. KRAMERER (Ann. de l'Inst. Pasteur, October, 1923, p. 886) brings forward evidence to show that this is not always the case. Using the *Spirochaeta cuniculi*, he inoculated a rabbit by scarification in the left fold of the peritoneal region. Seven weeks later spirochaetes were detected in this region. Spontaneous cure occurred, and three months later the rabbit was reinjected with the same strain as before, on the right side of the vulva. Seven weeks later a typical lesion was present at the site of inoculation containing spirochaetes. Two other similar experiments are quoted, in one of which, however, cure of the first infection was brought about by intramuscular injection of trypan. In another instance successful reinfection of the same rabbit was produced on two occasions; and in a further two animals, both of whom born of infected parents and both spontaneously infected, it was found possible to reinfect them with the same strain, after they had been cured of their primary disease. These results are of considerable importance, as attempts have been made to differentiate between distinct varieties of spirochaetes on the basis of cross-immunity reactions, it being assumed that reinfection with the same strain was impossible.

400. Effect of Vaccination against Diphtheria.

A. BACHMANN and J.-M. DE LA BARRERA (C. R. Soc. de Biologie, October 13th, 1923, p. 741) have made some successful attempts to immunize human beings against diphtheria. The vaccine they employed was a toxin-antitoxin mixture, which was not completely neutralized. The infection more than a local necrosis. In practice the vaccine was diluted 1 in 40, 1 in 16, and 1 in 5; 0.1 c.c.m. of the highest dilution was injected intradermally. It after forty-eight hours there was no reaction at the point of inoculation, the same dose of the 1 in 16 dilution was given, and so on till there was a definite reaction. Once this had been obtained—whether with one of the dilutions or with the pure mixture— the patient was given ten days' rest, which 0.1 c.c.m. of the same dilution as that which caused the reaction was injected. Altogether 16 subjects were studied carefully, the antitoxin of their serum being estimated at the beginning and end of the immunization, and again after 10 to 15 weeks. The results show that in 5 of these patients it was antitoxin titre attained a height of ten times its initial value, in 5 others a height of twenty times, and in the remaining 6 a height of fifty times its initial value. No intoxication is afforded as to how long the antitoxin remained in the blood.

401. The Phenolphthalein Test in Prostatectomy. NEGRO and COLASSETT (Journ. Urology, July, 1923, p. 12) discuss the phenolphthalein test as a means of establishing the safety of otherwise of prostatectomy. They state that this test, adopted for the last twenty years in various clinics, has given such good results that at the present time they never perform prostatectomy unless the percentage of phenolphthalein elimination reaches a figure which their experience has shown to be necessary for them to predict an immunity from those post-operative complications that result from prostatectomy. In 58 cases of enlarged prostate, 48 of which were submitted to prostatectomy, the results obtained by the phenolphthalein test with those given by the estimation of blood urea, and the determination of amylase content in each phorbate test with those given by the estimation of blood compared the findings obtained by the phenolphthalein test were submitted to prostatectomy. In 58 cases of enlarged prostate, 48 of which were submitted to prostatectomy, the results obtained by the phenolphthalein test with those given by the estimation of blood urea, and the determination of amylase content in each phorbate test with those given by the estimation of blood compared the findings obtained by the phenolphthalein test were submitted to prostatectomy.

tions—respiration, excretion, and nutrition, and though I mention nutrition last in the category it is probably first and foremost as a factor. The old process of what has been termed "skin nutrition by pigment" has no doubt, as regards the human body, passed away, and has been replaced by an internal nutritional digestive system. Nevertheless, the evidence of the old process still lingers with us. I admit that pigment is an intricate and tangled problem, but it is an agent in bodily metabolism which may be baffling but is none the less present. In an article that I published last year in the *Lancet* (vol. ii, 1922) I have put forward the view that cancer has possibly a pigmentary origin, and I think there is much to be said in favour of a thorough investigation of this hypothesis, for, as you say in your article, "the insidious change whereby a congenital melanoma assumes the character of a melanotic cancer remains a mystery, but research has shown that migration of branched pigmented cells may precede any sign of cancer." It is because I think that your leader limits too much the function of pigment in the biological world that I consider it may rather discourage a line of inquiry which, in my opinion, needs following up.—I am, etc.,

GEORGE THOS. BRATSON

#### ANTLERS IN DEER.

SIR,—In Sir William Macewen's address to the International Society of Surgery on "Antlers in relation to the growth of bone" (*BRITISH MEDICAL JOURNAL*, July 21st, 1923), and in Dr. T. Johnstone's letter (*BRITISH MEDICAL JOURNAL*, August 6th) the growth of antlers has been discussed by two members of the medical profession, using that term to include surgeons. I have given a good deal of attention to this matter as a zoologist, and perhaps you will allow me to offer some comments.

Sir William Macewen has a much greater experience in observations on the growth of bone than I can claim, but on the other hand I think he is not very thoroughly acquainted with the zoological literature concerning antlers, which he would have found discussed and summarized in two books of mine—namely, *Sexual Dimorphism* (A. and C. Black, 1900) and *Hormones and Heredity* (Constable and Co., 1921).

It is usual to describe the antlers as Sir W. Macewen does, as branched outgrowths of the frontal bones of the skull, but strictly speaking this is not quite correct. The bone forming the antler is developed rather as an addition to the outside of the frontal bone than as a growth from that bone. The frontal bone is a dermal bone, and is actually formed in development in the fibrous tissue of the derma, at least the fibrous connective tissue within which it is formed is to be regarded as merely a deeper layer of the derma. The antler is formed in exactly the same way, within the fibrous derma, but it grows acropetally, first at one point, and then at other points at the end of the branches, as well as in thickness, the skin and epidermis of course growing *pari passu*, and forming the so-called "velvet." Sir W. Macewen insists that the cutis (or derma) of the velvet grows directly on the bone of the antler without any intervening periosteum. I fail to see the distinction. In all ossification the osteoblasts are derived from a layer of fibrous connective tissue, in endochondral ossification from the dense layer which surrounds the cartilage, and afterwards becomes the periosteum, in the case of dermal or membrane bones from the fibrous connective tissue of the skin. When the dermal bone is developed the fibrous connective tissue surrounding its surface is the periosteum. In the case of the antler the derma and periosteum are continuous, as a necessary consequence of the mode of ossification. Therefore I do not see the significance of the statement that the cutis of the velvet grows directly on the bone of the antler without any intervening periosteum. The innermost layer of the cutis is the periosteum. Sir W. Macewen states that very little inosculation occurs between the vessels of the velvet and those of the bone in the antler. Caton, who devoted much attention to the study of the antler (*Antelope and Deer of America*, 1881), states that arteries pass in from the periosteum to the antler transversely as in long bones, but as the antler becomes mature the superficial layer of the

antler becomes solidified and the apertures which admitted the arteries become closed. Sir W. Macewen writes of two forms of ossification in the antler proceeding through the same base, which is cartilaginous. I cannot understand this statement, as I feel quite sure that there is no true cartilage at any stage in the development of the antler, or of the frontal bone with which it is connected.

I think there is no basis for the idea that the velvet exerts an inhibitive influence on the activity of the testis. Dr. Johnstone objects that if the testes are the *fons et origo* of the antlers why should their growth coincide with the quiescent state of the testes? The answer is that it has been shown that the hormone which stimulates the development of the antler is derived from the interstitial cells of the testis, not from the spermatic tubules. Moreover, when the testes are removed the normal development and shedding of the antler no longer take place. After castration of the adult the antlers are shed, and in the following spring they develop again, but the new antlers are not normal, they retain their velvet permanently and are never shed. The development of the antler, therefore, is not entirely dependent on the hormone from the testes, but the shedding of the velvet and the shedding of the antler are so dependent.

There can be no doubt that the shedding of the antler is due to the fact that at its base is dead. The pedicle is alive and covered with living skin, and phagocytes from the blood and lymph here attack the dead bone at the base, dissolve and absorb it so that the antler falls off. The next question is, What causes the death of the bone? The interior of the antler is spongy, but the base of it at the burr becomes consolidated and cuts off the blood supply, and so the bone dies. It would seem that the shedding of the velvet, which is rubbed off by the stag against trees while still vascular, is somehow connected with the death of the bone, for after castration the velvet remains and the antler is not shed, and the bony core of cattle which is covered with skin and horn corresponding to the velvet is never shed.

It would take too much space to discuss further the heredity and evolution of the antler. I will only remark in conclusion that it does not seem safe for a surgeon or physiologist to draw conclusions concerning ossification in general from observations on the antler, until he has thoroughly considered the physiology of the antler in relation to hormones and sex, and the question of its evolution.—I am, etc.,

J. T. CUNNINGHAM.

East London College, Mile End, E. Nov. 1st.

#### DIFFICULT MIDWIFERY IN GENERAL PRACTICE.

SIR,—Unfortunately at present the teaching of the various schools of midwifery is by no means uniform; there is no doubt that a general acceptance of whatever methods of treatment that give the best result would be followed by much benefit to the general public and advancement of the obstetric art.

With this object in view, I urge that some attempt to standardize treatment should be made. In the first instance we are faced with the difficulty of deciding which of the methods at our disposal will give the best result in a given type of case.

In order to facilitate comparison, I would advocate the publication, in one booklet, of the annual report of (say) six of the teaching hospitals in different parts of the country. The report of the maternity hospital with which I am most familiar usually consists of an introduction and statistics. In the former anything of note which occurred during the year is mentioned, and any departure from former treatment described, and the reasons for its adoption given. These six reports would afford a ready means of comparing results, and ultimately lead to a general adoption of the best methods of treatment. I am a believer in the value of internal pelvimetry, when indicated by the external measurements, or non-fixation of the foetal head at a time when it should be fixed. From the measurements thus obtained the pelvis is classed in that degree of contraction to which it belongs, and the appropriate treatment carried out. This method has considerable advantage over any other of which I am aware, in that it is as scientific, and exact, as is compatible with

A British Medical Association Lecture

MINOR ENDOCRINE DISTURBANCES

EFFECTS.

W. LANGDON BROWN, M.A., M.D. CANBARR.

PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL.

The last decade of the nineteenth century added greatly to our knowledge of the physiology of the ductless glands, while in 1903 Bayliss and Starling's discovery of secretin opened out the vista of a chemical control of the body, in which the nervous system merely acted as a trigger, firing off a series of reactions. This conception was elaborated until it bade fair to displace the nervous system from its supreme position, although Langley had already provided the antidote by his generalization that the action of adrenaline on any part was the same as that obtained by stimulating the sympathetic. But the far-reaching significance of that generalization was not yet appreciated. "The key to evolution lies in the continuous development of the nervous system," said Gaskell. Or, as Elliot Smith put it: "Man has developed and become the greatest of the premaria because of his faithful dependence upon the development of the brain." Considering the struggle the central nervous system has had to obtain control, it is not likely that it would abdicate its supremacy in favour of the more ancient dynasty of chemotropism.

We ordinarily think of the evolution of the nervous system as peacefully accomplished. A struggle for supremacy between two animals or between two species we recognize. But it would appear that a similar struggle accompanies the integration of the multicellular individual. Many apparently peaceful events in nature prove on closer analysis to involve a concealed struggle. Man is a gregarious animal, but he has not found it an easy task to adjust the desires of the individual to the needs of the community. Philosophers may lament this, theologians may attribute it to original sin, but it should lead the biologist to inquire whether the cells of which he is composed have always found it easy to sink their individuality in that of the organism. The thesis of a hostile symbiosis between the tissues of the body has been skillfully upheld by Morley Roberts. A strong central government is needed to keep order, and no high degree of differentiation is possible in the animal body without the control of a centralized nervous system, which has gradually acquired an increasing predominance. It is not too much to say that this control, though for the benefit of the body as a whole, may be resented by the individual tissues. Willard Trotter developed the argument of a hostility between nervous and somatic tissues, which is expressed in the way the former insulates itself.

Without defensive mechanisms no animal can survive in the struggle for existence, and no method of defence remains imperishable, for, if it were, the species possessing it would multiply to the exclusion of others. As evolution proceeded the apparatus for defence comes under the control of a central nervous system. Some defensive mechanisms, such as nettle cells, never become so controlled, but are replaced by other methods as the nervous system evolves. Certain primitive motor apparatus, such as cilia, also never come under such control, though they persist even in the highest animals. In general terms, a central nervous system enables very rapid reactions to occur, and the need for such rapidity of response will first be experienced in the struggle for existence, when its advantage is at once manifest. G. H. Parker, in his book on *The Elementary Nervous System*, has brought new observations into relationship with previously known facts, and has impressed upon us afresh that a nervous system starts as a series of

A British Medical Association Lecture (with revision) delivered before the South Essex Division of the Association at Southend-on-Sea on Friday, November 10th, 1932.

independent receptors and effectors in the deeper layers of the skin, the cells of which sink in deeper and deeper, until they become concentrated into a central nervous system. Between the receptor and effector an adjuster mechanism develops, which is the germ of the whole associative apparatus. In the vertebrates these internodal adjusters compose the chief mass of the central organs. It is not too fanciful to compare the origin of the nervous system to a group of settlers on the coast, who gradually invade the interior, first singly and then in an organized army, as in the nervous system of vertebrates which arises as a tubular invagination from the surface. Once established the invader assumes control over the indigenous inhabitants, fortifying itself as it goes and maintaining its protectorate by a system of rapid communication throughout the invaded areas. The biological and sociological parallel is remarkably complete.

A wise military occupation utilizes existing institutions, and the lowest level of the nervous system—that is, the autonomic or vegetative portion—enters into a close association with the older chemical methods of control. In my former lectures I have emphasized the fact that the endocrines which represent the specialization of these older chemical methods reveal their antiquity in the way they cling to vestigial structures. Indeed, with the exception of the pineal, these structures would appear to be homologous, and can all be traced to modified nephridia. In the course of evolution structural alterations have made them useless for their primitive excretory function and they have taken on a new function of internal secretion. Circumstances alter function. Thus we have hand in hand (1) an increasing concentration of the government in the hands of the central nervous system; (2) an increasing concentration of endocrine functions in glands which can no longer discharge their primitive functions.

I have also recalled the fact that the autonomic, vegetative, or visceral nervous system consists of two great divisions—the sympathetic and the parasympathetic or extended vagus. The former is labile, converting potential energy into kinetic and facilitating outward manifestations of that energy, while the latter is anabolic, directing energy inwards, where it is stored up. When these two are distributed to the same structure their action is always antagonistic, and when one is stimulated the other is inhibited. Each of these great divisions co-operates with a group of endocrine glands—the sympathetic with the adrenals, thyroid, and pituitary, the parasympathetic with the glands of the digestive organs and annexes. This is explicable since the former group are largely defensive, while the latter are concerned with obtaining energy from the food. The sympathetic is defensive not only against the external foe, but also against internal invasion by bacteria. Sympathetic through the ductless glands associated with it. This explains why (1) patients with endocrine defects stand better is a defensive mechanism largely controlled by the liver is a defensive mechanism largely controlled by the bacteria. The sympathetic is defensive not only against the external foe, but also against internal invasion by bacteria. Sympathetic through the ductless glands associated with it. This explains why (1) patients with endocrine defects stand better is a defensive mechanism largely controlled by the bacteria.

The endocrines are important regulators of metabolism. If metabolism is quickened up, hyperglycaemia usually results. This excess of sugar in the blood is normally used either to supply energy to the muscles or as a source of heat for the feeble reaction. Glycocalcaemia does not necessarily result, for there are two factors concerned in this—the amount of sugar in the blood and the threshold of the kidney. In fever this threshold is raised, so that the sugar poured into the blood by the thyroid, pituitary, and adrenals is prevented from escaping before it can be utilized. This is not only the case in fever, but whenever activity of the endocrine glands associated with the sympathetic is exaggerated. Thus in hyperthyroidism I have always found a higher percentage of sugar in the blood even if there is no glycosuria, and it is well known that the basal metabolism—that is, the metabolism per unit surface of the resting, fasting body—is increased.

If metabolism is slowed down fat and mucinoid material is deposited. Obesity is due to alteration in the balance between anabolism and katabolism. The commonest cause is taking more food or less exercise than the body requires, [3384]

a subject of this kind, and is quite sufficiently so for all practical purposes. Further, the obstetrician has the advantage of knowing (as far as possible) where he is, and what he is up against.

As another writer has mentioned, women frequently carry their children over time—especially is this the case in the minor degrees of contracted pelvis; hence it is of considerable advantage if labour can be safely induced by such means as the castor oil, quinine, and pituitrin method (Tweedy); or, as described in your columns. Should labour fail to ensue, there is no necessity to repeat the drugs for at least a week, and there is little likelihood of the patient falling spontaneously into labour for at least four days. In a breech presentation in a primipara, the first question should be, Is this presentation an accident, or is it due to a definite abnormality? If it is an accident, it is probably advisable to change it, whereas, if due to a minor degree of contraction, it were perhaps better left as a breech. The method of slow manual dilatation of the perineum to facilitate delivery, and avoid deep lacerations, might be worth a trial when much difficulty is expected.

The weak spot in the treatment of accidental haemorrhage by rupturing the membranes is that it may be a few hours before labour sets in, and the patient may bleed to death in the meantime. The great advantage of treating this condition by the vaginal plug is that, if properly applied, the bleeding will stop; but it has the drawback that it causes some degree of shock.

In transverse presentation, when called upon to decide between internal version and a destructive operation on the foetus, the condition of the child will form a useful guide. If the foetal heart is normal, or nearly so, version should be quite possible, but if the heart cannot be heard the child is probably dead, and there is no object in adding to the maternal risk out of consideration for it. When the condition of the mother and child are obviously bad the obstetrician will have to be guided by his experience and the circumstances of the case.

I do not know what success has generally attended the efforts to reduce occipito-posterior positions by means of abdominal pads, but it seems a method worth trying.

Even in the most outlying parts of the country the number of cases where it is necessary to perforate a living child must be very small. I do not think that occipito-posterior with a normal pelvis should be one of them.—I am, etc.,

R. E. TOTTENHAM, M.D., F.R.C.P.I.,

Dublin, Nov. 19th.

Gynaecologist to Dr. Stevens's Hospital.

SIR,—The very interesting paper by Dr. S. Gordon Luker (November 17th, p. 913) is particularly welcome because it deals with the difficulties of midwifery practice encountered by the practitioners who, during the very time of a difficult case, may have many another urgent call upon them. Like Dr. Luker, I, too, would pay a tribute to their ingenuity and resource.

The importance of ante-natal care needs no insistence, but it is perhaps not so often put to practical use in cases of slight pelvic contraction as it might be. After so much untutored and prejudiced criticism of omnopon-scopolamine it is pleasing to find what an ideal combination this is in such cases, allowing moulding of the head without the patient paying so heavy a price in fatigue—and certainly, therefore, actually helping to minimize the risks of post-partum haemorrhage. Experience has taught me many other such advantages following its use in conditions which used to be considered certain contra-indications to its exhibition.

Another direct outcome of ante-natal supervision is noted under "large size of the foetal head." For many years it has been my custom to attempt some estimation of the relative sizes of pelvis and foetal head at not later than the thirty-sixth week. The results have justified the extra trouble—many patients, who had had two (and in one three) stillbirths have had the third (and fourth) child living by a simple induction without the attendant possible risks of Caesarean section. These cases certainly do not call for a major abdominal operation. With these cases must be classed those of prolonged pregnancy: with

the knowledge to-day at our command it is wrong to allow any pregnancy to go beyond the calculated date for labour, especially as we can be quite reasonably sure of this date from abdominal examination.

Many readers will remember a writer recently advocating version in all cases which were not already breech presentations. Remembering the definite risks (which are real, if small) in any breech presentation as compared with vertex, and remembering, too, the rarer but serious risks such as extended arms with a breech, the exact converse, mentioned by Dr. Luker—that of converting a breech into a vertex—is much more reasonable. I can amply confirm Dr. Luker's opinion here, and the operation by external version is usually quite simple. As he says, "It is important to prevent breech labour in primigravidae."

Under the heading of ante-partum haemorrhage Dr. Luker says, "the patient is put to bed . . . and a hypodermic of morphine is given." But why not omnopon-scopolamine? It is better than morphine alone in every way. And, again, when speaking of post-partum haemorrhage he rightly draws attention to the importance of avoiding "a fair quantity of chloroform for a prolonged period." This administration, added to the "uterine exhaustion," due in many cases to difficult prolonged labour, is a strong factor in the production of post-partum haemorrhage. By administering omnopon-scopolamine throughout we have a certain means of reducing the necessity for much chloroform, and it also helps to prevent the uterine exhaustion, achieving the very objects we seek.—I am, etc.,

W. OSBORNE GREENWOOD, M.D., B.S.,

Harrogate, Nov. 22nd.

F.R.S. Edin.

SIR,—In a paper read before the Dover and Folkestone Division of the British Medical Association and printed in the JOURNAL of November 17th, 1923 (p. 913), Dr. S. Gordon Luker of the London Hospital makes certain statements when discussing "Difficult midwifery in general practice." It appears to be quite a pastime these days with certain of our teachers to convince us (general practitioners) of how very little we have absorbed of all the teaching in midwifery which these same teachers have flung at our heads during our student days. We stood humbly in the corner and accepted the many indictments showered on us at Portsmouth during the Annual Meeting, and now comes Dr. Luker to throw a few more stones; but, Sir, this time may I raise my voice in humble protest?

To quote Dr. Luker's own words, the students of less than twenty years ago acquired only a "sketchy knowledge of essential principles," so that no matter how skilful an accoucheur he may subsequently have developed into he is, in Dr. Luker's opinion, unfit, by his training, to tackle difficult midwifery! Dr. Luker, however, later on, reassures us with regards to the "student of the present day," who goes through a far more efficient and intensive training when he should be putting his super-knowledge into practice. Dr. Luker solemnly expresses the opinion that the "real remedy lies in providing sufficient maternity beds in hospitals in all towns"—rather a nasty jar for our supertrained modern accoucheur: it appears that even he is suspect!

Further on, Dr. Luker says, "What the newly qualified doctor of the present day finds difficult, is how to apply his hospital methods to general practice." Exactly so, and who is to blame for this but his teachers? It is their duty, and privilege, to teach him that science and art of midwifery that will enable him the best to deal with difficult midwifery whenever and wherever called upon. And it certainly does not help to reassure him or increase his confidence in himself to be continually told what a hopeless sort of idiot he is when dealing with difficult labour. In my humble opinion, the time has certainly arrived when practical midwifery should be taught by a general practitioner, and not by a "specialist." Speaking for myself, I learnt more midwifery of the useful practical sort from general practitioners than ever I learnt from my specialist teachers, and Dr. Luker's own words appear to bear out the general truth of my statement.

Finally, when discussing the treatment of unreduced occipito-posterior positions, Dr. Luker says . . .

in *thyroid obesity* the increase in weight is not all due to fat. The heavy folds running from the nose to the cheeks, the bags under the eyes, and the supraclavicular pads are all very characteristic. The condition is really a minor degree of myxoedema, and presents a similar harsh dry skin with a marlar flush. The mental lethargy is as marked as the physical.

In *pituitary obesity* the whole face is rounded, with a smooth, soft skin, while the colour is usually fresh or unduly high. I called it the "Dutch doll" type, and then found Reardon had previously referred to it as the "padding face." The amount of hair on the face and body is much reduced. Fat is specially deposited on the shoulders, breasts, hips, and thighs, giving the latter a "plus four" appearance. The skin over the posterior borders of the upper arms and on the legs below the knees is a mottled red. The way this mottling stops abruptly just above the olecranon is very characteristic. These people bruise very easily and there is some polycthæmia. In women there is often amenorrhoea; but that is not the cause of the polycthæmia, as I found it in a typical case in a boy of 16. The mental outlook is often bright, active, and cheerful.

In *Dermat's disease* there are localized deposits of fat which are painful—they are particularly likely to occur on the posterior borders of the arms and the axor aspects of the thighs. Here the mental condition is usually one of great depression, which is not merely due to the pain of the lumps, although this may be considerable.

In some cases of *pituitary tumour* there is both an insatiable appetite and great sleepiness; the patient wakes to eat, and having eaten falls asleep again. It is not easy to be sure what determines the bright alertness of one group of fat hypopituitarism and the profound somnolence of the other, but I suspect it depends on whether there is increased intracranial pressure or not. The fat boy in *Pichette*—"That that boy, he's asleep again!"—is usually quoted as a classical example. A few years ago a very fat Jew, weighing 20 st., turned up at St. Bartholomew's Hospital at 11 p.m., complaining that he felt very sleepy. Fortunately he had a doctor's card with him; I cannot help thinking that a fat Jew complaining otherwise I should have received more advice than treatment. It was a good thing he was admitted, for he had a syncopeal attack soon afterwards. X-ray examination showed enlargement of his pituitary fossa. Under injections of 1/2 c.cm. of pituitrin three times a day he lost 2 st. in ten days and his general condition improved remarkably. Quite recently I advised two daily doses of 1/2 c.cm. in a similar case, with the result that 17½ lb. were lost in twelve days.

*Thyroid Obesity*.—The thyroid is an infantile organ; if it persists after it should have vanished we find it is antagonistic to the development of the gonads, and hence indirectly leads to the deposit of fat. The thyroid type tends to have rather a long face, with clear skin and good features, marked by the precocious development of a double chin. It constitutes the lymphatic type of the older physicians, or status lymphaticus as we prefer to call it to-day. Such patients are liable to paroxysmal dyspnoea, the so-called thymeric asthma, and they respond to infections badly. *Gonadal Obesity*.—Recently I saw a girl of 22 who was very stout, and who presented some features of the pituitary and thymeric type, and even some signs of thyroid degeneration. I noted that her upper lateral incisors were very small. She was surprised when I guessed that her periods began late. The guess was correct, for they did not start until she was 16½. One or both undeveloped upper lateral incisors are often associated with gonadal degency, and her obesity showing signs of several endocrine glands

### THE ADRENALS.

Having considered some of the effects of the endocrine glands on general metabolism, I will turn to some results of minor disturbances of these glands, with reference to the psychological aspects. It is clearly recognized that the medulla of the adrenal is really represents the post-ganglionic element of the sympathetic nervous system, which explains Langley's generalization, to which I have already referred. The chromaffin cell and the sympathetic cell migrate out of the ce originally much more widely distributed. The cortex, on the other hand, represents a group of nephritic, and arises from the Wolffian body. It is very significant that this we may trace the extraordinary effect that cortinoids or overgrowth have in producing premature tumours or overgrowth. We shall see that each of the different endocrine has its own tendency to tip the balance towards vir or feminism. What the advantage may be of this association of two structures of such widely different or we cannot say, but the persistence of the association in all animals above the level of fishes suggests that it is great importance. Apparently, if this association fail to occur in foetal life the brain remains at the fifth stage neoplasia does not develop, and an unrecognizable no results.

Since adrenalins can raise blood pressure and glycosuria, it is tempting to assume that these conditions occurring in later life are due to overactive the adrenal medulla, produced by nervous strain or emotional sort. But proof of this is lacking. The classical picture of underaction of the adrenal medulla is Addison's disease, and it is possible that adrenal exhaustion may play a part in war neuroses and other functional characters characterized by myasthenia, vasomotor instability, and blood pressure. I should like to say a few words on the psychological of adrenal disturbances. Fear is really a perversion of defensive mechanism. It is the intensification of the instinctive process called into activity by danger. But just a cannot conceive that all the primitive sensations of a animal have the affective intensity of pain as we expect it, so we must not regard the emotional response o animal to danger as having the affect of what we by fear. To do so would be to fall into the common error as Parker says, of interpreting the activities of the sin animals as though they were miniature human beings. much scarier associative mechanisms in the nervous system of lower animals precludes such an idea. An imagination writer, A. C. Benson, says: "It is strange to note the perpetual instinctive consciousness of danger which besets birds in the open; they must live and, her obesity showing signs of several endocrine glands

tion cannot be performed" (by manual rotation of the head) "tentative and judicious trial of axis-traction forceps may be made. If the head does not descend with gentle traction (the italics are mine) perforation of the head should be performed." In fact, we are asked to kill a living child, for in nine cases out of ten it is living, as I have time and again proved by extracting with forceps after a very severe pull. Not only has the infant been alive and undamaged, but has lived to develop into a strong and active child. Moreover, the mother has not shown those dreadful injuries which our specialist teachers say are bound to occur. I can assure Dr. Luker that after an experience of midwifery ranging over twelve years, and including many unreduced occipito-posterior positions, I have never yet failed to deliver an undamaged and living infant, and very often it has only been after a prolonged and severe pull with the forceps.—I am, etc.,

Bradford, Nov. 24th.

VINCENT NORMAN, F.R.C.S.Ed.

#### ANTE-PARTUM HAEMORRHAGE AND ECLAMPSIA.

SIR,—In reply to Professor James Young (November 17th, p. 945) I beg to deal with two points: the first concerns the relationship of concealed accidental haemorrhage with eclampsia; the second, the statement "that the acute and often extreme distensions of general medical and surgical practice are never associated with eclampsia." Professor Young quotes my view as to the first—"that the distension of the womb by the accumulating blood causes toxæmia by pressing on the kidneys and other abdominal organs." He states, "this view is disproved by the fact that there may be intense toxæmia where the concealed clot is no bigger than an apple"; and by the occurrence of abdominal distension in practice without eclampsia.

Of course, if eclampsia only occurred in cases of ante-partum haemorrhage, there would be force in Professor Young's criticism; but eclampsia may arise in the absence of ante-partum haemorrhage of any kind whatever. Professor Young states: "If anything is clear it is that in the eclampsia both of accidental haemorrhage and of placenta prævia there must be some common factor." The point is that there must be some factor common (yet peculiar) to all cases of eclampsia. Professor Young does not recognize this; he limits his inquiry to cases of concealed or unconcealed accidental haemorrhage. The occurrence of eclampsia in other types of case—namely, in primigravidae, in strong muscular and (otherwise) healthy pregnant women, in unmarried pregnant women, in cases of twin pregnancy, in hydramnios, and in certain cases of hydatidiform mole—without any abnormal position of the placenta (indeed without a placenta) and without any intrauterine haemorrhage at all, negatives his view. These cases put his conception, already discredited by other considerations, completely out of court—they show that placental separation, wherever the placenta, is not a cause of eclampsia.

As regards the second point, I may say that the error of expecting eclampsia or "uraemia" with the distension of intestinal obstruction is referred to in a small forthcoming volume; and the criticism dwindles down to the occurrence of abdominal distension with ovarian cysts and fibroids without eclampsia. It was Matthews Duncan—he who believed in the retentive power of the abdomen, and attributed to the suction of the thorax the elevation of the uterus in pregnancy, and the retraction of the partially born child's head between the pains—who first advanced this objection. In a footnote in his translation of Braun's book on *The Uraemic Convulsions of Pregnancy, Parturition and Childbed* (1857), Duncan stated that "the influence of simple pressure by the pregnant uterus seems to be much exaggerated"; and that "in ovarian dropsy, fibroid tumours, and a variety of other affections, no such result is observed from a pressure exactly like that of the gravid uterus, and often more severe and longer continued." Professor Young (like so many other obstetricians) accepts and repeats this criticism. He thinks it demolishes the mechanistic conception of eclampsia; he believes (presumably) that the pressure resulting from the growth of the pregnant uterus is "exactly like" that due to the growth of an ovarian cyst or fibroid tumour. But he is in error; he has at least omitted one consideration—the

difference in effect on the abdominal wall with these two different kinds of growth. In the one (pregnancy), the recti become separated, as a rule by a considerable interval; in the other, separation either does not occur or is inconspicuous. I showed in my paper of 1913 that the separation of the recti in pregnancy could only be attributed to a greater contraction than normal of the transversales abdominis; and that this change postulates the conception of a raised pressure in pregnancy. Similarly, the absence of this separation with ovarian cysts and large fibroids shows the absence of such rise of this pressure. If the pregnant uterus with its increase in volume does not cause an increase of pressure in pregnancy, how explain the separation of the recti? If the separation in pregnancy is due to a mere yielding, a mere weakening, how explain the non-separation with fibroid tumour and ovarian cyst? A week ago I removed a fibroid tumour of the uterus weighing 32 lb.; the girth of the abdomen was 50 inches; there was no separation of the recti, or it was negligible. Yet am I to believe that the pressure within the abdomen—produced at the wash-tub and by carrying in the breakfast things—was as great as that produced with a smaller distension in pregnancy, with the muscles spastic, during similar movements?

Professor Young's argument is incomplete in his survey of the incidence of eclampsia; and as far as the mechanistic conception of eclampsia is concerned, does not touch fundamentals. It is plain he has not considered at all the abdominal wall in pregnancy; nor the pressure conditions which reign within the abdomen during this state.—I am, etc.,

London, W., Nov. 17th.

R. H. PARAMORE, F.R.C.S.Eng.

#### VACCINATION PROPAGANDA.

SIR,—Dr. Killick Millard still stands on his head on the vaccination question; what a pity that such a respected medical officer should have side-slipped on this question. Everyone else is wrong and Dr. Millard is right. Assuredly there were 42 cases in the Poplar outburst, but instead of deducing that infantile vaccination should be given up, Dr. Millard should fight for revaccination at the age of 18 to 20, or thereabouts.

Dr. Millard honestly believes that the first cases of small-pox in a totally unvaccinated (never been vaccinated) community would be diagnosed at once and so everybody in the infected zone would be saved by swift vaccination. I deny his contention absolutely and wholly. It is playing with fire to imagine that the first case would be certain to take to bed at once. There is every likelihood that such a patient would move about for some hours, at any rate, and make Poplar's 42 cases insignificant in comparison with the number which would accrue. A man is a gambler who says that only one or two first cases would suffer and that every contact would be rounded up rapidly by the modern practitioner and the modern medical officer of health.

Will Dr. Millard please answer this: Suppose that I advise all parents in Deptford to give up vaccinating their babies and suppose the people were foolish enough to follow this advice. An outbreak takes place and two lads of 10 years are the victims. They become so ill that nobody could miss the diagnosis, and they die, not having been vaccinated. What am I to say to the father when he comes to the Town Hall and asks me whether it is true that vaccination prevented the contacts from contracting the disease, and if so, why was the same theory of prevention not applied to his dead children when in their infancy? Am I to say that I am an apostle of Dr. Millard and that we believe that a few deaths must be expected and accepted so long as the rest are saved? Will that satisfy the parents?

I claim that these two or three deaths are unnecessary, as unnecessary as the deaths or injuries inflicted by one or two doctors who are not so clean in their vaccinal methods as they should be. Can it be possible that Dr. Millard has unearthed his theory to placate the antivaccination stalwarts in Leicester? Let us hope at any rate that no others will fall from grace and plunge into this mirage of vague indefiniteness.—I am, etc.,

CHARLES S. THOMSON,  
Medical Officer of Health.

Deptford, Nov. 22nd.

"capacity." This patient showed all these points. But it is a little difficult to explain why even while the pituitary was actively stimulating growth there was a failure of the moral senses and intellect to develop. In the present state of our knowledge we can only say that there may have been a diversion of the pituitary action in one direction at the expense of others. Dr. Critchton Miller has suggested to me that it is rather due to failure on the part of other endocrine glands. In connexion with Berman's view that the posterior lobe is concerned with the affections, it is interesting to note that this youth had never shown the slightest affection for anyone. It had been suggested that he should be certified as of unsound mind. On that I wrote to his doctor as follows—and it happened to be just a fortnight before Ronald True's case:

The sufferer from pituitary disturbances seems to compensate for his feeling of inferiority by craving for the "fat boy in *Pickwick*." The craving of the "fat boy in *Pickwick*" was to make people's "flesh creep." The parts intermedia of the pituitary, which is developmentally part of the anterior lobe, is concerned with carbohydrate metabolism. If it overacts there is excess of sugar in the blood and sometimes frank glycosuria; if it underacts the blood sugar is low and carbohydrate tolerance is high—no doubt this plays a part in the obesity of hypopituitarism. When the anterior lobe with the parts intermedia is in

1. The first step is to identify the problem. This involves understanding the current situation and the goals that need to be achieved.

We are on safer ground in asserting that the secretion of the posterior lobe stimulates plain muscle and is often found to be an excellent stimulant in a certain type of atonic constipation. I am convinced, too, that diabetes insipidus is generally due to defective action of the posterior lobe. Clinical and pathological evidence strongly supports this view, and injections of pituitrin will control polyuria. Apparently this is due to direct action on the kidney; but I must not stop to discuss this point.

Several recent observations have thrown considerable light on the influence of the pituitary on carbohydrate metabolism. Thus Mackenzie Wallis<sup>1</sup> has found the blood sugar raised.

The thyroid is essentially a feminine gland, and it is developed from the nectus of the paleoestracan ancestor. Its enlargement at puberty, marriage, and pregnancy, its readiness to involution at the menopause, all point that way. It has been called the gland of creation. Some time ago Crichon Miller asked if anyone had ever heard of a

That overaction of the anterior lobe produces acromegaly in adults is well known. It is also generally recognized that some lesion of this lobe plays a large part in the osteitis deformans of later life. Overaction of this lobe in early life when general growth is still possible produces gigantism. Minor degrees of increased action of the anterior lobe results in a tall bony man, long in tooth and big in jaw, with large broad hands. He often has a good intellect, with an imaginative force which can be controlled and brought to the service of his active brain; he is often musical—in short, a practical visionary. Unfortunately the effect of an overactive anterior lobe is not always so balanced as to produce such a happy result. Thus in the following case the amount of pituitary disturbance was not great, though the effect on character was disastrous.

A young man of 23 was brought to see me who had been very late in learning to walk and talk. He showed me two photographs of himself taken at the age of 4 or 5; one of these looked like a normal child, while the other looked degenerate. By the age of 6 he had developed the habit of lying. He grew rapidly to the height of 6 ft. 5 in. His palatal arch was very high, and his knuckles and wrists were very large. He was a confirmed liar and thief, and was suspected of deliberate and willful arson.

Gigantism due to overaction of the anterior lobe before the epiphyses are united may be followed by degeneration of the gland. The fossa becoming too small for the gland the patient is apt to develop moral and intellectual inferiority, to suffer from compulsions and obsessions, and to lack inhibitions. As Berman puts it, such individuals are "pathological liars with little or no initiative or conscience. . . . As children they lie and steal, have enuresis, science.

**THE PITUITARY.**

## GARDEN CITY SANITATION.

Sir,—Dr. Hindhede's contention in the lecture an account of which was published last week (p. 996) is to the effect that the sanitary engineer keeps us in bondage and will not allow us to dispose of sewage in a remunerative way. This is interesting, and I hope you will allow me to reply. In theory Dr. Hindhede may be right, but in practice his plan is difficult to carry out. Dr. Hindhede does not seem to understand that there is only one "Garden City" at present in existence (by name Letchworth), though another (Welwyn) is just starting. Letchworth is an industrial town which has a population of 13,000 people. The people here nearly all come from other towns, been used to town life and amenities, and their object in living in Letchworth is to carry on industry under tolerable conditions for health and enjoyment. The houses all have gardens in the town, and these gardens are mostly cultivated and produce large quantities of vegetables and fruit. During the war the potatoes produced in Letchworth were a real addition to the food of the town. We have found that too large a garden is not a blessing to industrial workers. It would soon be an offence to public health to have a town like this without a proper sewage system. In the early days one or two people in the "town" area tried a "Poore" system of disposal, but they soon had to give it up. On the "agricultural" belt surrounding the town it is possible to do without sewage, but even then we find that smallholders wish to avail themselves of the town system if they can get on to it. My experience is that even in country villages the people dislike cesspools, and though the dry earth closet system is the ideal it needs constant supervision. If, on the other hand, town dwellers are to live in the country—and the crying need of to-day is for the people to get out of the big cities into the country—the services of the sanitary engineer will be necessary.

The Garden City is not a cranky idea, as Dr. Hindhede might lead one to suppose, but is a very sound practical solution for much of our social trouble of to-day.—I am, etc.,

NORMAN MACFADYEN.

Letchworth, Hertfordshire, Nov. 21st.

## Obituary.

ARCHIBALD SLOAN, M.B., F.R.F.P.S.G.,  
Glasgow.

THE late Dr. Archibald Sloan began his career as a teacher, but after a few years turned to the study of medicine. He graduated at Glasgow University, and some years later was elected a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow. He was a member for many years of the British Medical Association. My own acquaintance with him began when I was a medical student, and in the intervening years I saw very much of him and his work. He always endeavoured to look at questions from the viewpoint of "the other man." He was generous to a fault, sparing neither time nor money nor strength in his efforts to benefit others, or to assist those who were in pecuniary need. He had a remarkably fine intuition of clinical facts, and his resourcefulness at the bedside was singularly conspicuous. He was always interested in youth. He rejoiced in demonstrating "a case" to his young medical friends. He began practice in a crowded industrial locality, and though he was far from robust the amount of work he accomplished was extraordinary. He was exceedingly well known in that neighbourhood, and his professional brethren frequently sought his advice. For a few years he was casualty surgeon to the police. Later he became outdoor physician, and latterly assistant physician, to the Glasgow Maternity Hospital. He was also for several years dispensary physician to Anderson College Dispensary, later known as the Central Dispensary.

As his professional status became confirmed, Dr. Sloan retired from these posts, and began once more to interest himself in educational matters. He became a member of the Glasgow School Board, and devoted much time to the subject of physical training. Later on he was appointed

medical officer to the students under the Glasgow Provincial Committee. In this position his ripe clinical experience was of great value, not only to the students, but also to "The Department."

In every position he occupied he endeavoured to benefit the moral as well as the physical welfare of those who came under his professional care. In some few cases, when disagreeable things were said to him (as they are to all of us), he would assume an expression of such complete stolidity and impenetrability that his detractors were baffled. At other times he would speak and act in such a way that it seemed to his friends as if he deliberately wished to be misunderstood. For the clerical profession he had much sympathy, and his professional services were freely and generously bestowed on many, not only in his own well loved denomination, but in all. It was characteristic of him that in his last illness, when nearly too ill to speak, he inquired anxiously for the welfare of a patient whom he had visited four days or so earlier. To a most unusual degree he retained the affection and confidence of his patients, and some of those whom he had visited in the early days of his practice remained on his "list" to the very end. In the closing months of his life it became more abundantly evident that his guiding principles were deep-seated and far-reaching. He was indeed a man who lived and died in the exercise of humble Christian faith.

My own debt of gratitude to him is very great, so great that I cannot attempt to describe it. Professionally he taught me much, and in very many other ways I owe him more than I can express.

JOHN RITCHIE, M.B.

## Universities and Colleges.

## UNIVERSITY OF LONDON.

At a meeting of the Senate held on November 21st, Mr. W. E. Lo Gros Clark, F.R.C.S., was appointed as from January 1st, 1924, to the newly instituted Readership in Anatomy at St. Bartholomew's Hospital Medical College. Mr. Lo Gros Clark, who was a student at St. Thomas's Hospital, served with the R.A.M.C. during 1918-19, and during 1919-20 he was demonstrator in anatomy at St. Thomas's Hospital. Since 1920 he has been Principal Medical Officer at Sarawak, Borneo. He has published papers on ancient Eskimo skulls and on the Paeonian bodies.

The D.Sc. degree in embryology was conferred on Miss Margaret Tribe, of University and King's Colleges, for a thesis entitled "The Development of the Hepatic Venous System and the Postcaval Vein in the Marsupialia."

It was resolved that the Physiological Laboratory Library should be kept together as part of the University Library and be developed in connexion therewith as a memorial to the late Professor A. D. Waller.

The following candidates have been approved at the examination for the Diploma in Psychological Medicine, with special knowledge of Psychiatry:

B. W. Brown, H. E. Brown, Isabel F. Kinn, T. Lindsay, J. Wall.

## NATIONAL UNIVERSITY OF IRELAND.

THE following candidates have been approved at the examination indicated:

M.B., B.Ch., B.A.O.—J. J. O'Reilly, G. F. Duggan, T. Prendergast, P. J. Kerley, H. Faul, Anna G. Brereton, J. Callaghan, M. J. Canty, D. M. Clune, E. J. O'Shea, Jessie N. Cooke, W. J. Coyne, H. J. Croghan, P. G. Dooley, Honoria J. Doyle, A. R. J. Duggan, M. Farrell, E. S. Foley, Elizabeth M. Foley, B. Gallagher, T. Glynn, C. Godfrey, G. J. Hanly, J. P. Harington, P. J. J. Hughes, G. J. Joyce, J. S. J. Joyce, P. P. Keogh, W. J. Kerrigan, T. J. Lynch, K. L. McColgan, Mary J. McEvoy, Sarah A. McGee, F. McKernan, E. McManus, J. M. McNamara, T. W. Moran, Mary M. O'Flanagan, Cecilia Phillips, L. D'A. Quigley, Mary B. Quinn, Mary Ryan, Teresa M. Scott, T. Skokos, Anne Sullivan.  
Exempt from further examination in Part I (Medicine and Pathology).—Catherine M. Barry, W. Bolton, J. G. Cooney, A. E. B. Kirby, Winifred M. O'Hanlon.  
Exempt from further examination in Part II (Surgery, Ophthalmology, Midwifery).—Bergin, C. V. Connolly, T. J. Cusack, M. F. Dodd, Mary K. J. B. Hurley, Anne G. Kehoe, J. Anne M. O'Dowd, Pauline K. O'Flanagan, P. J. O'Grady, T. E. Pierce, E. L. Sharpe, J. Travers, Nora Wallis.  
D.P.H.—Mary J. Farrell, M. A. McInerney.

\* First-class honours. † Second-class honours.

ROYAL COLLEGE OF SURGEONS OF ENGLAND.  
Annual Meeting of Fellows and Members.

We have received the following further letter (see page 1009):

Sir,—As mover of the second resolution at the annual meeting of the Royal College of Surgeons of England on November 15th, I should like to be allowed to make a few remarks in connexion with the question of admitting Members to

Both the external and internal secretions of this gland are anabolic in their effect. The external one prepares a foodstuff for absorption; the internal one is not proved to lead to the utilization of sugar by the tissues. It is the special merit of Banting's work that he has been able to isolate the active principle of this long-sought-for and long-sought-for internal secretion. It would appear to act by changing glucose into another form,  $\gamma$  glucose, which it can be used. When it is absent or diminished more or less of the sugar in the blood remains in a non-assimilable form and is bound sooner or later to be excreted into the urine. How soon it appears will depend on the response of the kidney, which tends to raise its threshold when there is excess of sugar in the blood, thus allowing a longer time for the diminished pancreatic internal secretion to act. This internal secretion, insulin, is not confined to the pancreas. It is probably widely spread, and certainly appears to be present in great at a particular phase of its life cycle (Winter and Smith). This is no the place to discuss the therapeutic use of insulin, but it is already clear that it lowers blood sugar, diminishing ketosis, and raises the respiratory quotient. By converting glucose into a form in which it can be used it naturally prevents its accumulation in the blood. It is of great

As already stated, the activity of this gland is normally limited to the infantile period. It appears to act as a brake on the development of sexual maturity, presumably in the interests of somatic development. Since no interrelationship has been obtained from the thymus it is not easy to see at present how it antagonizes the gonads. Possibly this is achieved through its influence on the structure of the blood, for the appearance of the adult blood picture and the disappearance of the thymus are usually simultaneous. While the thymus exists the characteristic blood reaction is lymphocytosis, and it is only during this period that we meet with the condition known as "splenic anaemia," or "splenic anaemia merely the reaction of infantile blood to various severe toxemias. In the thymic stage, as it is stated by various authors, is simply a part of a general enlargement and an enlargement. It may be that this is a sign of an abnormal sensitivity to foreign proteins, which is a characteristic of those whose responses is exaggerated. This would account for the inability to dyspnoea, syncope, and anaphylactic shock associated with status lymphaticus. When the adult blood picture is reached this lymphocytic reaction is replaced by a leucopenia in anaphylactic shock.

THE THYRUS.

calcium content of the blood. The first effect has been recently used by Vines to estimate the activity of parathyroid secretion, and the same observer by direct estimation of the calcium in the blood. Applying these facts to clinical observation Grove and Vines found in the case of lesions which could be watched, such as parietal ulcer on the leg, that calcium was an important factor in their healing, that parathyroid extract was capable of influencing calcium metabolism, raising a deficiency in it to normal, and that with a normal calcium content healing speedily occurred. They then applied the method to internal lesions such as gastric or duodenal ulcer, with similar results. They believe that calcium deficiency is an index of the absorption of a toxin, and that in all the various diseases improved by parathyroid therapy the common factor is sepsis. It is suggested that the benefit is derived from a stimulation of the leucocytes since the polymorph count rises, probably from an indirect effect of calcium on the blood plasma.

seat on the Council. If the Council can be convinced that it is in the interests of the promotion of the art and science of surgery that Members be represented on the Council, the argument would be a very strong one; the legal aspects of the matter or the democratic point of view does not interest them.

When it is remembered that a certain number of Members in the bigger centres do their own surgery, and that practically all the provincial hospitals, except in university towns, are staffed by general practitioners, it will be realized that their interest in the advancement of surgery is probably equal to that of the Council, added to whom we have the Members scattered all over the Empire, who mostly do their own surgical work. All these men have to do their work under more arduous and trying conditions than those on the staff of teaching hospitals, and they know the special difficulties that confront them as general practitioners.

The aim of the College is not only to turn out Fellows, but also to make capable general practitioners—by far the larger number, and equally important from a public point of view—and surely suggestions and recommendations from these men in general practice would be of help to the Council. The Council teach in the medical schools and finally examine the students, but they do not know the end-results of their work, and that can be remedied by giving Members some representation—I am, etc.,

HOWARD M. STRATFORD,  
F.R.C.S.Eng., M.R.C.S.Eng.

London, W., Nov. 23th.

SIR,—In the account of the annual meeting of Fellows and Members of the Royal College of Surgeons in last week's issue, the President is reported as "saying" that "he had paid very careful attention to the answer he would give," whereas, what actually happened was that he merely read a previously prepared statement which had no reference whatever to what had transpired at the meeting itself. The President's reply was merely a repetition of the contentions put forward at last year's meeting by the then president, and made no reply to the complete refutations made both by Dr. Nash and Dr. Roche. Your readers should also know that the President's reply was received with chilling silence!

It is truly amazing that the Council of the Royal College of Surgeons cannot even now see that a co-operation of Members and Fellows in the government of the College would be to the benefit of all concerned.—I am, etc.,

London, W., Nov. 23th.

C. E. WALLIS.

## The Services.

### ROYAL ARMY MEDICAL CORPS.

#### Examination for Commissions.

AN examination for not fewer than forty commissions in the Royal Army Medical Corps will be held on January 30th next. Applications should be made to the Secretary of the War Office not later than January 20th, and the presence of candidates will be required in London from January 23th. Meanwhile those intending to compete can obtain a full statement of the duties and emoluments of the service on making written application to the Secretary, War Office, Whitehall, London, S.W.1.

## Medical News.

A BRONZE tablet in memory of the late Mr. Charles Wray has been erected at the Croydon General Hospital. The tablet, with medallion portrait, is the work of Mr. H. J. Youngman, and bears the following inscription: "To honour the memory of Charles Wray, F.R.C.S.Eng., who for thirty-five years was ophthalmic surgeon to this Hospital. This monument is set up by his patients as a token of love and gratitude."

The French Minister of Public Instruction has introduced a bill for the purpose of awarding to Madame Curie a pension of Fr. 40,000 per annum, in recognition of her scientific work. It is proposed that the pension shall be conferred on December 28th—the twenty-fifth anniversary of the announcement of the discovery of radium by Madame Curie and her late husband.

A COURSE of five lectures on "The influence of environment on the life of bacteria" will be given by Mr. F. W. Twort, M.R.C.S., L.R.C.P. (Superintendent of the Brown Institution), in the theatre of the Royal College of Surgeons of England, W.C., on December 11th, 13th, 17th, 18th, and 19th, at 4 p.m. Admission is free without ticket.

DR. R. C. FIELD of Roos, near Hull, has been presented by his friends and patients with a mahogany grandfather clock, an album containing the names of the subscribers, and a cheque for the balance of money collected, as a mark of their regard on the occasion of his retirement from practice in Roos and district.

A MEETING of the Metropolitan and Home Counties Maternity and Child Welfare Sub-Group of the Society of Medical Officers of Health will be held at 1, Upper Montague Street, Russell Square, W.C.1, on Friday, December 7th, at 5.30 p.m., when Dr. J. W. Carr will read a paper on signs and symptoms of tuberculosis of the respiratory system in children under five. The meeting is open to all members of the medical profession.

THE Harben Lectures at the Royal Institute of Public Health will be given on December 11th, 12th, and 13th by Professor Dr. Levaditi, M.D., of the Institut Pasteur, Paris. The first lecture will deal with neurotropic virus (encephalitis herpes), the second with neuro-vaccine, and the third with new discoveries in the treatment and prophylaxis of syphilis. All interested are invited to attend these lectures, which will be given at 37, Russell Square, London, W.C.1, at 5 p.m. each day.

A FESTIVAL dinner in aid of the Royal Northern Group of Hospitals was held at the Mansion House, London, on November 21st, under the chairmanship of Admiral of the Fleet Earl Beatty. In proposing the toast of "Success to the Hospital" Lord Beatty mentioned the progress made since its humble origin sixty-seven years ago. The group of hospitals into which it had grown—the Royal Northern Hospital in Holloway, the Royal Chest Hospital in City Road, the Hospital of Recovery at Southgate, and the Beckett Convalescent Home at Clacton-on-Sea—served a population of more than a million in an area of seventy square miles. Of the 375 beds possessed by the group, 70 had had to be closed owing to a debt of £50,000. The chairman's appeal for generous support for the associated institutions was supported in an eloquent speech by Miss L. M. Faithfull, late Principal of Cheltenham Ladies' College. The Marquess of Northampton (chairman of the hospital), in responding to the toast, expressed thanks to the Lord Mayor for granting the use of the Mansion House, and referred to the forthcoming opening of the new casualty department by the Prince of Wales, president of the group. The health of the Lord Mayor and Corporation was proposed by Sir Philip Sassoon, seconded by the Rev. Basil Bourchier, and acknowledged by the Lord Mayor. The Secretary, Mr. Gilbert G. Panter, then announced that the donations in response to the present appeal amounted to £11,643. A successful evening closed with the health of the Chairman, proposed by Lord Biddell and supported by Mr. G. B. Mower White, emeritus surgeon to the Royal Northern Hospital.

A FESTIVAL dinner in aid of the appeal for funds by the London Jewish Hospital, Stepney, was held at the Connaught Rooms on November 26th under the chairmanship of Sir Humphry Rolleston, K.C.B., President of the Royal College of Physicians of London. About seven hundred were present. After the Royal toasts had been duly honoured and letters of regret read from those who had been prevented from attending, the chairman proposed the toast of the "London Jewish Hospital." He said that the old familiar saying that it was more blessed to give than to receive was very appropriate on the present occasion, for in the past the Jewish Hospital, like any other hospital in London, had given far more medical help and surgical skill than it had received financial consideration. The institution was founded in 1867, and though still in its teens was full of promise and was doing good work. The crowded East End of London was poor in hospital beds; the number of patients seeking admission to the 50 beds was at the rate of £80 per annum, which indicated that the number of beds ought at least to be doubled. A proof that the hospital was unsectarian was afforded by the fact that of the 52,000 out-patient attendances in 1922 no less than 40 per cent. were other than those of the Jewish faith. There were Italian, French, and German hospitals in London, and he saw no reason why there should not be a Jewish hospital. Sir Humphry Rolleston added that he could most emphatically bear testimony to the excellence of the medical, surgical, and nursing staffs, and he hoped that the appeal for funds would meet with generous support. The Very Rev. Dr. M. Gaster, in responding to the toast, said that the doors of the hospital were always open to the sick and suffering without any questions being asked as to their creed. Mr. I. Berliner, who also responded, gave statistics showing the growth of attendances of patients since the opening. The toast of "The Guests" was proposed by the Chief Rabbi, the Very Rev. Dr. J. H. Hertz, and that of the "Medical Profession" by Mr. H. H. Haldin, K.C., the latter being acknowledged by Sir John Blund-Sutton, President of the Royal College of Surgeons of England, and Dr. J. Burnford, senior physician to the hospital. It was announced that the donations received and promised had reached the sum of £5,000.

DR. G. B. GRIFFITHS, Medical Inspector of H.M. Prisons, has been appointed one of the Commissioners under the Prison Act, 1877.

interest to observe that the avidity of the tissues for this form of glucose is so pronounced that an overdose of insulin leaves insufficient sugar in the blood for immediate needs. Too little blood sugar is more disastrous than too much; the former immediately produces acute symptoms; the latter is compatible with fair health for years. The effect of insulin on ketosis is very marked, for even on a rigid protein and fat diet the diabetic may show no reaction for diacetic acid in the urine—another evidence of the oxidizing power of a glucose. The rise in the respiratory quotient inevitably follows the more complete utilization of carbohydrate.

I may remark that while the discovery of insulin completely proves that the cells of the pancreas form an internal secretion which promotes the assimilation of sugar, it does not prove that all diabetes is due to a pancreatic lesion. The fact that pituitary extract can antagonize insulin provides new support for the view that diabetes may be due to a more profound and subtle disturbance of metabolism than a lesion of one gland.

Swale Vincent has reminded us that organotherapy is often employed without any rational sanction. As he says, it would be difficult to mention a drug which is clearly and beyond doubt of value in the treatment of disease and yet which possesses no known pharmacodynamical effects. Yet many of the extracts in common use have not been shown to have such action. Even some of those which do, cannot be satisfactorily used in substitution therapy. The early triumphs of thyroid medication tended to blind us to the difficulties surrounding the use of other glandular extracts in therapeutics. Yet the thyroid is exceptional in containing a definite reservoir of secretion and, by virtue of its duct originally opening into the alimentary canal, retaining the power of having its secretion absorbed by that route. It is perhaps fortunate that many of the preparations in use are inert, for otherwise damage might be done. Thus the injection of secretin by liberating an active pancreatic secretion may produce digestion of the intestine. It is just as well, therefore, that organotherapy lags behind endocrinology. But I feel sure that Swale Vincent, while rightly demanding more exact experimental methods in organotherapy, reaches too agnostically a position with regard to endocrinology. Here the careful study and comparison of abnormal types by clinical methods may be of considerable help. To that study I hope some of the foregoing observations may contribute.

## SOME HINTS FROM THE OLD PHYSICIANS.

AN ADDRESS DELIVERED BEFORE THE BRADFORD MEDICO-CHIRURGICAL SOCIETY, OCTOBER 17TH, 1923.  
 BY  
 JAMES ALEXANDER LINDSAY, M.A., M.D.,  
 F.R.C.P.,  
 ASSISTANT PROFESSOR OF MEDICINE IN THE QUEEN'S UNIVERSITY OF BELFAST.

Imaginary cures which long held the field, and we shall learn to be more careful in appraising every new medical doctrine and every new method of treatment which to-day makes its appeal to us. We shall learn that time is the great test and negatively, the history of medicine is the greatest test and experience the only safe guide. The history of medicine is to-day coming into its own. There is now an International Society for the Study of the History of Medicine, which has already held three successful congresses. Charts and lecture-ships in the history of medicine have been provided in the various universities. The FitzPatrick Lectures at the Royal College of Physicians have produced many valuable monographs, and the time is near when some knowledge of the history of medicine will become a necessary portion of the medical curriculum.

Scientific medicine begins with the Greeks. They were the first to study medicine as a lay subject, to free it from superstition and priestly authority, to practice bedside observation on scientific lines, and to develop a sound therapeutic. Whether they owed much or little to Egypt, Babylonia, or Crete, we have no certain information. When and a cult of the God of Healing—Asclepias—and a society of physicians—the Asclepiadae. The chief centres of this cult were at Trilakia in Thessaly, in the island of Cos, at Pergamos in Ionia, and at Epidaurus in the Peloponnese. The temples of Asclepias were practically hospitals and sanatoria. They were usually placed in localities favoured with climatic and hygienic advantages, and often in the neighbourhood of mineral springs. The chief means of cure were physical exercises, baths, imunctions, purgatives, emetics, dietetic regulations, rest, and various modes of suggestion. It is instructive to note that in the very earliest times the Greek physicians understood and stressed suggestions. They knew well the great influence of mind upon body. In the temples of Asclepias one of the favourite methods of treatment was the temple sleep. In the silence of the night hours the physician, personating the God of Healing, visited his patients, soothed their fears, encouraged the hope of recovery, and no doubt favourably influenced the course of disease. Whether he taught them to say "I am feeling better and better every day," "I am unable to attain," or "I am not sure that Freud, Jung, Adler, and their numerous followers might not have found some of their views and methods anticipated by the disciples of Asclepias. The wheel has come full circle, and modern psychotherapy is reverting to the practice of Cos and Epidaurus.

Hippocrates is the first great figure in the history of medicine. He belonged to the great age of Greece, the age in which saw such astonishing achievements in literature and in art. Born in the island of Cos in the year 460 B.C. of a family of Asclepiads, he travelled widely, acquired all the medical knowledge of his time, practised in various cities of Greece, and achieved great renown in his own time, and even greater fame in succeeding ages. Galen called him "the divine," and he is justly regarded as the Father of Medicine. His works cover the whole field of medicine, surgery, and obstetrics, and are an encyclopaedia of the best knowledge of his day; and he gave physicians the highest ethical inspiration which medicine can possess. The famous Hippocratic oath is an ideal of medical practice which can never become obsolete. Hippocrates left descriptions of the epidemic fevers of Greece, phthisis, epilepsy, puerperal diseases, warning from their mistakes and failures, and successes, warning from their labours, sacrifices, and their pioneers, its seers, its heroes, and its martyrs. We can derive encouragement from their labours, sacrifices, and successes, warning from their mistakes and failures, and their pioneers, its seers, its heroes, and its martyrs. We can derive encouragement from their labours, sacrifices, and successes, warning from their mistakes and failures, and their pioneers, its seers, its heroes, and its martyrs. We can derive encouragement from their labours, sacrifices, and successes, warning from their mistakes and failures, and their pioneers, its seers, its heroes, and its martyrs.

Hippocrates was the first great clinical physician and the founder of the bedside method. His anatomy was weak, his physiology weaker, and his pathology weaker, but he was an observer of the first order, and he had a sane and profound intellect. He studied diseases objectively, without theory, and recorded his successes and his failures with equal impartiality. He relied upon experience. Hippocrates achieved three great objects: he freed medicine from superstition; he systematized and expanded the best medical knowledge of his day; and he gave physicians the highest ethical inspiration which medicine can possess. The famous Hippocratic oath is an ideal of medical practice which can never become obsolete. Hippocrates left descriptions of the epidemic fevers of Greece, phthisis, epilepsy, puerperal diseases, warning from their mistakes and failures, and successes, warning from their labours, sacrifices, and their pioneers, its seers, its heroes, and its martyrs. We can derive encouragement from their labours, sacrifices, and successes, warning from their mistakes and failures, and their pioneers, its seers, its heroes, and its martyrs. We can derive encouragement from their labours, sacrifices, and successes, warning from their mistakes and failures, and their pioneers, its seers, its heroes, and its martyrs.

The patient still remained in an extremely critical condition; the temperature was intermittent, the pulse rate remained high, and the respiration rate averaged about 50. It was decided that the only hope of saving the patient's life lay in giving iodine as intensively as possible. Accordingly the following treatment was instituted: (1) The right pleural cavity and the pericardium were irrigated twice daily with a solution containing collosol iodine (Crookes). (2) Potassium iodide was given by mouth (25 grains three times daily), but later this was changed to iodopin 1 dr. thrice a day. (3) Collosol iodine was given intravenously. The doses were as follows: 10 c.cm. on the first day; 20 c.cm. on the third day; 30 c.cm. on the fifth day; 50 c.cm. on the seventh day; and 80 c.cm. on the ninth day. This maximum dose was repeated at two-day intervals so long as any non-thrombosed veins could be discovered. It is interesting to note that no symptoms of iodism appeared during the course of the treatment. During all this time the patient was very ill and his dyspnoea and intermittent fever continued.

On November 2nd x-ray examination showed that the chest was much clearer; on November 14th the temperature showed signs of settling down, and a few days later became normal. The discharge from the drainage tubes became less and less, and the ray fungus more and more difficult to find. Early in December it was decided to give the patient an autogenous vaccine of *Staphylococcus aureus* derived from the pericardial discharge; injections of this vaccine caused a great reaction, and the empyema wound began to give trouble again. A probe discovered loculated pus, and its removal gave great relief. Again abdominal distension occurred, and albuminuria, which had been present before, became more marked. About December 12th it was obvious that the patient had developed acute nephritis. The urine diminished to 16 ounces in twenty-four hours, and general anasarca with ascites appeared. The urine was examined by Dr. H. S. Pemberton, who reported: "Protein in very large quantities (vast preponderance of serum albumin over serum globulin). All kinds of casts—epithelial mainly—leucocytes and red blood corpuscles present." Paracentesis abdominis was performed on three successive occasions, and 31, 32, and 28 ounces respectively were withdrawn. The fluid was yellow, contained no organisms, and coagulated on standing. Shortly after this the urine cleared up, the anasarca disappeared, and the patient became comfortable again, although the respiratory rate still varied between 36 and 44.

From this time onwards the patient never looked back. Between December 24th, 1922, and February 6th, 1923, he gained 30 lb. in weight. Repeated radiograms were taken, and all showed a great and increasing improvement in the chest condition, though the right diaphragm remained raised.

The serum Wassermann reaction was completely negative, and blood urea estimation showed 15 mg. per 100 c.cm. of whole blood.

On his discharge from hospital on February 13th, 1923, the condition was as follows: General condition very good, no fever, urine contains a slight trace of albumin. The drainage wounds are all healed except for a very small sinus in the pericardial incision. The heart appears normal except that the apex beat is about half an inch outside the nipple line in the fifth space.

As regards the further progress of the case extracts from the patient's letters are interesting. On March 6th, 1923, he wrote to say that he was as well as he had ever been before his illness, but that the sinus was still discharging a bead of pus. This was dressed and potassium iodide was taken regularly.

On May 16th he reported that the sinus was healed, and that he was so well that he intended to resume his work in Canada.

#### Remarks.

How and where the actinomycosis infection was contracted is a complete mystery. The man was employed in a cardboard box manufactory in Canada, and previous to that had been in the army and had seen active service on many fronts. While on military service he had looked after horses, and it is possible that the infection was contracted at that time and that it had remained dormant until his attack of pneumonia. It is certain that the infection was quite recent so far as its clinical manifestations are concerned, for the man was in apparently normal health on sailing from Canada. Whether the original focus was in the liver with extension to the lung through the diaphragm, or whether it was primarily pulmonary, it is impossible to say.

The patient's recovery was little short of miraculous, as on many occasions his life was despaired of. Despite recent criticisms upon the potency of collosol iodine, it would appear that in this case the drug was of great value and played an important part in the recovery. It is, of

course, impossible to draw conclusions from one case, but we feel that by publishing this note other workers will be encouraged to persevere in more intensive iodine treatment in the fight against this almost mortal infection.

There can be no doubt that the very recent infection in this case, together with the patient's extraordinary pluck and vitality, were most important factors in his recovery.

In conclusion our thanks are due to Mr. Rawlinson for his surgical procedures and to the numerous colleagues who aided and encouraged us in what appeared to be a hopeless battle.

## SUCTION IN THE TREATMENT OF SEPTIC EARS.

BY

W. STUART-LOW, F.R.C.S.,

CONSULTING SURGEON, CENTRAL LONDON THROAT AND EAR HOSPITAL.

It is essential that the practitioner, who in almost all cases has the patient suffering from a discharging ear under his treatment for some time, it may be for months, should realize the disadvantage, not to say danger, of aural syringing. He sees the patient in the earliest stages, and has a much better opportunity than the specialist, who commonly only comes on the scene after the trouble has been long established or complications have arisen.

The intricate anatomical arrangement of the middle ear and its accessory recesses is favourable to bacterial activity. The best known methods of combating bacillary ravages in this region, other than a surgical operation, consist of forcibly syringing out accumulated discharges, and the instillation of antiseptic drops. But the risks involved in syringing out the middle ear in the presence of a chronic discharge are very great. This is aptly illustrated in the case of cholesteatoma. Even the advocates of forcible syringing invariably add a word of caution when dealing with this. Usually, in cholesteatoma, especially if it has arisen, as is almost invariably the case, after prolonged sepsis, there is found an enlargement of the normal aural cavities and mastoid cells, and any watery lotion, if powerfully injected, can easily be driven far afield into the recesses. The effect of syringing is to cause swelling of the semi-desiccated accretions and accumulations, and pressure on the surrounding brain and labyrinth. All watery fluids encourage septic change and bacterial growth.

I have seen many cases in young children, in whom the syringing of running ears has been ordered, where the immediate result of a more than usually forcible injection by the child's mother has been acute mastoiditis and abscess. Indeed, but few cases of acute mastoiditis in children have come under my notice where syringing has not been the customary treatment, with the result that an immediate cortical mastoid operation which might otherwise have been unnecessary was rendered imperative. I cannot, therefore, condemn syringing too emphatically. I wholly disapprove of syringing the ear in the presence of a discharge. I order my patients boracic wool, with directions to twist it up and to wipe out the ear as often as necessary. Syringing may have the effect of driving the sepsis further afield, and on into the most dangerous positions, such as the attic, aditus, antrum, and mastoid cells, becoming in this manner a cause of abscess over the mastoid region. Owing to my dissatisfaction with all forms of ablation and irrigation, and with much of the instillation of ear drops that is still so popular, I have for some years been employing suction to get rid of discharge from the ear and its annexes. This suction method of thoroughly clearing the septic ear of discharge is so successful, that I am anxious to bring it prominently to the practitioner's notice, who, as he sees these patients in the earliest stages of the trouble, can adopt it with more telling effect. The suction method is so easily applied and is so safe and effective that it is eminently adapted to the use of the busy and overworked medical man; and, if adopted by him, would serve to prevent so many septic ears drifting into a serious condition and the patient having to be sent

suddenly to hospital for operation. It is where such emergency operations have to be performed, always in a dirty pus-saturated field, that fatal complications such as septic meningitis are likely to arise.

The simplest method of applying suction to the aurial cavity is to attach to the nozzle of a medium-sized glass syringe or a larger metal syringe a short length of rubber tubing which must be inserted into the ear, the piston being drawn out to allow all purulent material to be sucked away. The action is the reverse of syringing, and the addition of the rubber tubing preannounces. Until the ear is dry this method must be repeated with the aid of a good reflected light, which is always desirable. The use of a motor suction pump, with special air pointed glass tubes bent in several directions, under a good light is a more elaborate and effective method. These tubes may be inserted, under a good light, into the many recesses of the tympanic cavity, up into the attic, down into the depressed floor of the tympanic recess, and back into the

For acute otitis media following paracentesis tympani, all the pus from the middle ear may be sucked out by inserting a finely pointed tube into the incision of the membrana tympani. This treatment, added to the application of bell-shaped dry cups over the mastoid, I continue at intervals for forty-eight hours, a mastoid operation not being thereby avoided, provided the treatment is used without delay during the inflammatory and congestive stages. For chronic aurial suppuration suction is employed in the cavity over the mastoid, and over the site of the exit of the mastoid vein passing out directly from the lateral sinus; it should be repeated once or twice or even thrice a day for at least one month. This method, when carefully carried out, has, with very few exceptions, the effect of avoiding operative treatment. The system of suction is the means of clearing the ear of discharge so effectively, that it prepares and secures a clear field for operation, should this be necessary, and prevents the most dangerous complication—septic meningitis.

## Memoranda: MEDICAL, SURGICAL, OBSTETRICAL.

### A CASE OF BLASTOMYXOSIS.

The following case, which was reported to the Norwich Medical-Chirurgical Society, seems of sufficient interest to warrant publication.

Mr. R. first consulted me on May 12th last with regard to an eruption on his face. A casual glance gave the impression that he was suffering from impetigo contagiosa, but on closer inspection and after listening to the history I was forced to alter my opinion. He was in Germany for a considerable period and returned home at the end of November last. Shortly afterwards he had what he described as a boil on the left-hand corner of his mouth; the boil grew to a head, was there a month, and then burst, leaving a cavity. Being suspicious that this might be a case of fungoid infection, before attempting any treatment I sent him to the Pathological Laboratory for a report, which was negative in every particular. The cavity had been removed, the resemblance of the after the hard scabs had been removed the resemblance of the condition to the illustration facing page 221 in the latest edition of Norman Walker's *Dermatology* became so strikingly obvious that, being convinced that this was a case of blastomycosis, I again sent him to the laboratory for a report. The second report, together with Norman Walker's description of the condition, I think, clinches the diagnosis.

Dr. W. B. Christopherson's report is as follows: Examinations have been made by the caustic polish method, Gram, and other stains. The films were complicated by the presence of starch granules, but structures strongly resembling blastomycosis are present. By the caustic polish method a few double-contoured bodies are seen (apparently not starch granules), as found in Warrick's cases. These he named *Odium cordoides*. There appears to be strong evidence either of blastomycosis or of a closely allied granulomatous condition.

Norman Walker points out that in his first edition he referred to this condition as a rare form of tuberculosis, of which he had seen two or three cases.

\*Masters Allen and Habburns of Wigmore Street have made these special

### INFLUENZA COMPLICATED WITH ACIDOSIS AND RASH IN A CHILD.

Consultant, Norwich. F. STEPHEN, M.B., Ch.B.

During the last few years several cases have been observed, particularly in America, and pathological examination has half the cases. The affected part was covered with a number of contiguous papillomatous elevations, which were more prominent at the margins and from between which pus exuded. The change from the diseased to the normal skin was very abrupt, the condition having a well defined margin.

I did not notice, probably for want of careful observation, the presence of the halo mentioned by Walker, nor was I quite satisfied that the margin had a bluish-red sloping border. I may mention that Mr. R. is a lover of horses, and I think it probable that this is how the infection arose.

I prescribed fairly large doses of potassium iodide internally. Leaving the small patch on the forehead as a control, I applied local treatment to the corner of the mouth, the left nostril, and to the patch at the junction of the cheek and left wing of the nose. The local treatment consisted of starch powders to remove the scabs, followed by a thorough swabbing with "Fecto," a concentrated form of Dakin's solution made by Parke, Davis. It was found that although the scabs in the centre of the lesion could be removed by this method, those on the margin were more tenacious and had to be scraped off with a sharp spoon.

To date the scabs have ceased to re-form, the purulent discharge has come to an end, and the centre of each patch is beginning to assume the appearance of healthy skin, whereas the small patch on the forehead has not been modified.

In conclusion I would point out that the prognosis is not good. In some instances death has occurred. No actual case of cure is reported, and so far modification of the condition has been the only result of treatment, according to Norman Walker.

Consultant, Norwich. F. STEPHEN, M.B., Ch.B.

I was asked to see a girl, aged 6, who complained of headache. She had always been healthy, except for a definite history of acidosis with coma and vomiting three years previously.

The temperature was 103° F., the pulse 130, and the respirations 20. The conjunctivae were injected, the tongue of strawberry type, the throat somewhat sore, and the cervical glands of both sides enlarged but not tender. The heart was normal. The breath sounds were bronchial and a few scattered rales were present. The reflexes were normal, but the patient was listless and irritable. There was no vomiting or diarrhoea. The urine was intensely acid and free from albumin.

The clinical features of the case were those of uncomplicated influenza.

The treatment was on simple lines. Solid food was withheld, and water was freely given, together with a mixture containing potassium citrate and ippecacuanha wine. Ten grains of aspirin were given over a period of two days.

On the third day a rash appeared. Bright red papules and macules encircled the neck, extended behind the ears, and covered the flexor surfaces of the arms, the inside of the thighs, and the buttocks. The rash presented some of the characteristics of the rash of measles and of scarlet fever, but was not typical of either. It was very irritable, and in places became raw and painful. The temperature and pulse rate remained high, but the general condition was good.

In view of the history the question arose whether the case was one of acidosis or an aberrant type of scarlet fever or measles. Dr. Ford Cargill, of the London South-Western Fever Hospital, kindly saw the patient with me five days after the onset of illness. He was of opinion that the rash was not that of any of the exanthemata, but was due to acidosis. Cold sponging, large quantities of water, and full doses of sodium bicarbonate (15 grains of every four hours) were ordered, and in forty-eight hours the pulse and temperature were normal, and the rash had faded.

There seems no doubt that the patient had really suffered from influenza. Her young brother had simultaneously a

septicaemia, epidemic parotitis, and many other diseases—descriptions to which modern medicine has little to add. His account of wounds, fractures, and dislocations is wonderfully accurate. He was the first to compile regular clinical records. His examination of the patient included the facial expression, the pulse, the temperature (estimated by laying on of hands), the respiration, the sputum, the urine, localized pains, the movements of the body. He emphasized the importance of inspection. He noted the ominous significance of picking at the bedclothes. He described that grave aspect of disease which we still call the "facies Hippocratica," and that important sign which we know as Hippocratic succussion. He also described a sound in the chest which he compared to "a creak like that of leather"—probably pleural or pericardial friction. He recognized healing by first intention. He attached great weight to prognosis and wrote a special work on the subject.

In his therapeutic Hippocrates relied much upon the *vis medicatrix naturae*. He used few drugs and those sparingly. His favourite methods were fresh air, rest, careful diet, baths, purgation, soothing draughts, massage. Is it too much to say that to-day we are witnessing a turn of the tide towards the simple and gentle Hippocratic therapy, as contrasted with the violent practice of the Middle Ages and later? Hippocrates did not try to expel disease by force—rather to assist Nature in her efforts after elimination. "Natural powers are the healers of disease" is one of his maxims. He advised that wounds should be irrigated with water of the greatest purity, or with boiled water—a foreshadowing of the aseptic practice of to-day. He insisted that the hands and the nails of the operator should be carefully cleansed. His successors too often forgot or ignored these wise directions.

Hippocrates had sound views on public health. He wrote a book upon "airs, waters, and places," which is the first book, so far as we know, on the subject of medical geography, climatology, and anthropology—subjects to which he attached the greatest importance. One of the "aphorisms" affirms that "the body can only be understood as a whole"—a hint against the possible dangers of excessive specialism.

Hippocrates has left a message to all of us to-day—the importance of careful bedside observation; the need to study medicine in the light of experience and not to be hidebound by theory; the wisdom of helping rather than coercing the healing powers of Nature; the necessity for a high ethical ideal for the healing art.

Plato was much interested in medicine, but he was not a practising physician, and he had more regard to the soul than to the body. Perhaps the chief lesson which we can derive from his works is the influence of mind upon body—a doctrine much inculcated upon us to-day. He puts this doctrine in a somewhat extreme form in the following passage in the *Charmides*:

"I dare say you have heard eminent physicians say to a patient who comes to them with bad eyes that they cannot cure the eyes by themselves, but if his eyes are to be cured, the head must be treated, and then again they say that to think of curing the head alone, and not the rest of the body is the height of folly . . . and, therefore, if the head and the body are to be well, you must begin by curing the soul."

I should like to submit this passage to a jury composed of equal numbers of ophthalmic surgeons and psycho-analysts.

Aristotle was the son of an eminent physician and was much interested in medicine. His work on the subject has unfortunately been lost, but he gave medicine the foundations of zoology, comparative anatomy, and embryology. He was the first great biologist. His *Historia Animalium* is a marvellous collection of facts relating to the structure, functions, and life-history of nearly all the animals of his country and time. Recent work has shown how accurate was his observation.

Alexandrian medicine, in which the two leading names are those of Herophilus and Erasistratus, made some advances in medicine, especially in anatomy. Herophilus was on the track of the correct view of the circulation of blood, but failed to solve a problem which had to wait many centuries for Harvey. The school of Alexandria developed a tendency to polypharmacy; many remedies imported from the East came into use and stimulated a method of practice which had baneful results in the Middle Ages. Toxicology occupied

a prominent place in this school and probably owed its inspiration to the East. It had a somewhat sinister aspect. Mithridates, the famous King of Pontus, who probably derived his information from Alexandria, is said to have immunized himself against poisoning by means of the blood of ducks fed on poisonous materials, a curious anticipation of some modern doctrines.

Celsus, a Roman gentleman in the reign of Tiberius Caesar, left an elaborate work, *De Medicina*, which had considerable influence upon medical thought and practice. Of his aphorisms the following may be quoted:

It is not to be thought that he should know the remedies of disease who does not know their original causes.

We ought not to be ignorant that the same remedies are not good for all.

Laziness slackens and dulls the body, but labour strengthens and makes it firm. The former hastens old age; the latter prolongs youth.

Idleness and luxury first corrupted men's bodies in Greece, and afterwards afflicted them in Rome.

Galen is the greatest name in ancient medicine after Hippocrates. A Greek and a native of Pergamos in Asia Minor, he practised at Rome in the second century of our era. A man of boundless energy and industry, of eagerness and curiosity in the pursuit of knowledge, a keen observer, he made large advances in osteology, myology, and the anatomy of the nervous system. His physiology was vitiated by the doctrine of vital spirits, and his pathology by the doctrine of the four humours. His therapeutic was largely governed by the theory that disease is something which must be expelled from the body—a *materia peccans* which must be got rid of. Hence his emphasis upon methods of elimination. Another of his theories was that disease must be combated by remedies exercising counteracting influences—for example, cold by warmth, plethora by deprivation—the doctrine of *contraria contrariis*. He attached much weight to housing, the influence of air and light, gymnastics, dietetics, cold and warmth, massage, baths. He advocated change of climate in certain cases. As forms of exercise he mentions rowing, digging, mowing, throwing the javelin, running, jumping, hunting, splitting wood, carrying burdens. He advised exercises for the cure of adiposity. He advised baths in fevers. He had sound views upon diet. He employed venesection, leeches, laxatives, emetics, diuretics, and diaphoretics.

Galen's influence on medicine was almost omnipotent for a thousand years. His views on anatomy and physiology paralysed research until overthrown by Vesalius. His doctrine that disease is something to be expelled from the body by blood-letting, purgation, diaphoresis, and other eliminative measures had a long career and still has weight in medical practice. It lies behind many familiar therapeutic methods. It is the foundation for some modern medical theories. "Toxaemia" is almost as blessed a word in medicine as was "Mesopotamia" in the story of the old lady who found comfort and satisfaction in that geographical expression. It is worthy of reflection how far this Galenic doctrine is, or is not, too preponderant with us. Is it really true that the colon is a human sewer which Nature has unhappily preserved as part of our anatomy? Is it the *fons et origo* of a large proportion of our woes? Should we get on more comfortably without it? I need hardly remind you that bacteriology has given this doctrine a new orientation. We have now the problem set to us: Are we likely to be more successful in our struggle with disease by attempting to destroy and evacuate our invisible foes, or by aiming at fortifying the patient's natural powers of resistance? Our therapeutic methods will be much affected by the answer which we give to this question. Galen stands for coercing Nature. Hippocrates stands for supporting Nature. A wise therapeutic will strive to find the *via media* between these two complementary conceptions.

In the early Middle Ages medicine was largely in the hands of the Arabian physicians. In the West the healing art had been overtaken by a long night. While the Arabian physicians spoke Arabic and practised the Moslem faith, many of them were Syrians, Persians, or Jews by race. Their medical lore was Greek in origin, but had travelled by devious routes to Baghdad, Jundi Shapur, Bokhara, Egypt, Cordova, and Toledo. Amongst the most

In Dr. Hinds Howell's experience patients who had suffered a mental change did not tend to improve. "The clever child who had become stupid and the "easy" child who had become "difficult," he was afraid, remained more or less in *status quo*. Parkinsonian symptoms formed the next largest group. They were present in 15 cases of the 28, and naturally varied a good deal in extent. One might find a limited type of this condition, the face only affected, or the rigidity was so extensive and severe as to make any voluntary movement impossible. Disorders of gait in the more severe cases were of course common, festination, propulsion, and retro propulsion occurring characteristically. Tremor had not been observed so frequently as rigidity, and when present was not usually of the paralytic gait type. Often incontinent, it was brought out by emotional excitement and was as rule of a coarse type involving the whole limb. Not infrequently it was unilateral. Ocular defects came next, having been met with in 11 cases of the series. The commonest disability was lack of convergence with paralysis of accommodation, but persistent squint, usually an external strabismus, lack of upward movement of the eyes, and myoclonic movements had occurred fairly frequently. Disorders of sleep did not form a very prominent group in this series. Drowsiness during the day occurred in 5 cases—insomnia in 1, but in addition to these there were 3 cases which exhibited a reversal of normal sleep tendencies, diurnal somnolence to a very marked degree being followed by nocturnal excitement. All three cases were children and in each these symptoms were present during the acute stage of their illness and had persisted. The children went to sleep only in the early hours of the morning and then passed into what amounted to a state of coma, from which they were aroused with very great difficulty. In one, that of a girl aged 20, about three months after the acute illness there developed an attack of dyspnoea which lasted for about three weeks; she improved for a few weeks and then remained much as before; her respirations were 36 per minute, the pulse rate 80; these respiratory troubles had now ceased and the girl was in active employment, quite recovered. A second case exhibited a type of respiration which, although not of the true Cheyne-Stokes type, at times seemed to approximate

the mental disturbance varied very much. At one end of the scale one found merely a slight loss of emotional control or emotional response, whilst at the other one found a mental state bordering on dementia. None of the cases, however, had had to be placed in asylums. Loss of emotional response was common. "I have forgotten how to laugh" was a common complaint; unfortunately for them fewer had forgotten how to cry! Slowness of the mental processes, corresponding so often with slowness of physical reaction, was also common enough. Impulsive thoughts and actions had been noticeably present in 2 cases, both of them of the Parkinsonian type; one was a child who performed unexpected actions, the result of impulse, explained them by saying that she was behaving as she did in order to get well; the second was a woman, aged 23, who had on more than one occasion narrowly escaped suicide. Express trains and bridges under which water was rushing excited an extraordinary influence over her. She told him: "I don't want to die, but when I see a train rush past I feel I simply must throw myself in front of it. I don't know why I should." It seemed as though, exaggerated by her physical limitations, she found an almost irresistible attraction in the rush of water or of concentration train. One other case exhibited loss of power of concentration and memory to an amazing extent. She could repeat the substance of a sentence two minutes after

in seven cases. Over one-quarter of the affected with "symptomatic paralytic rigidity" were more common than tremor. Progression was very frequently associated with several weeks or months after the acute phase of the illness. In contrast to the involvement of the trunk and limbs in variety, were prominent. These movements developed early and showed a tendency to improvement. Sensory loss was rare, being case only, but pains in the trunk and limbs were seen of this dreadful disease the more did a necessity of giving a guarded prognosis about 20 per cent. during the initial acute inability to permanent and even progressive considerable and relapses might occur. The fortunately was still symptomatic.

famous names are those of Rabban, Rhazes, Ali Abbas, Avicenna, Rashid, Avenzoar, Averroes, and Maimonides. Many of these physicians were prolific authors, and the *Continens* of Rhazes, the *Liber Regius* of Ali Abbas, and the *Canon* of Avicenna long enjoyed a great popularity. The last of these works is still an authority in some parts of the East. The Arabian physicians were inspired by Hippocrates and Galen. From the latter they derived most of their ideas regarding anatomy, physiology, and pathology, while in therapeutics they were guided largely by the Hippocratic tradition with its emphasis upon hygiene. They attached much weight to diet, baths, rest, climate, cleanliness, etc. They were fully alive to the influence of suggestion. Two stories have been handed down to us which illustrate this last point. Rhazes had at one time under his care the Amir Mansur, who was suffering from some obscure malady which had resisted the ordinary methods of treatment. Rhazes determined to try a little psychotherapy. He appeared suddenly in the Amir's tent with a sword in his hands, and threatened to kill him. The Amir was naturally incensed beyond measure by this extraordinary proceeding on the part of his physician, and endeavoured to seize Rhazes, who escaped with difficulty. The story goes that the Amir was cured of his malady. Avicenna once had a patient who suffered from the delusion that he was a cow and ought to be slaughtered for food. Avicenna told him that he was much too thin for the butcher, and that he must be fattened before slaughter. The patient was directed to consume large quantities of milk; he recovered his physical health and lost his delusion. Rashid, who practised at Tabriz, excelled in materia medica, a department to which the Arabian physicians made some contributions of value. He dealt largely in aromatic oils—violet, jessamine, narcissus, rose, myrtle, orange, mastic, clove, cardamoms, cassia, fumitory, betel.

The lore of the Arabian physicians reached Western Europe mainly through Spain, and there is reason to believe that the rise of the medical school of Montpellier was due in large measure to Arabian influence. The Moslem seats of learning made progress in chemistry, and this progress probably reacted upon medicine. Averroes and Maimonides represent the more philosophical side of medicine. Both were eminent philosophers as well as famous physicians.

One of the most interesting chapters in the history of medicine relates to the rise and fame of the medical school of Salerno, near Naples. Its origin is obscure, but there is reason to believe that it owed something to the traditions of Greek medicine which had lingered in Southern Italy and Sicily, something to the Arabian physicians, and something to the Jews. Its origin may be traced to the ninth or tenth century, and it became the most famous medical school in Europe during the early Middle Ages. The spirit of the school was Hippocratic. It prized clinical observation, relied upon experience, and practised a simple therapy based upon that of the Father of Medicine. The emphasis was upon diet, hygiene, baths, ventilation, and such like measures. Patients flocked from all parts to this medical shrine, which was a bright spot in a dark age, and many cures were effected. Salerno was famous for its traditions and aphorisms. Of the latter I may quote one—

Si tibi deficient mediei, mediei tibi fiant  
Haec tria: mens hilaris, requies, moderata diaeta—

an admirable piece of advice. It reminds us of Burton's recommendation of Doctor Rest, Doctor Quiet, and Doctor Diet.

Medicine entered upon a new era with the publication in the year 1543 of the great work of Vesalius, *De Humani Corporis Fabrica*, in which he overthrew the authority of Galen and placed human anatomy upon its modern footing. His work had an immediate influence upon surgery, and was the guide of Ambroise Paré, the greatest surgeon of the Middle Ages. Paré was distinguished for his practical sagacity and robust common sense. He was influenced by the Hippocratic tradition and believed in the *vis medicatrix naturae*. He practised amputation on scientific lines and reintroduced the ligature of arteries which had fallen into disuse in the Middle Ages.

Harvey's discovery of the circulation of the blood is the greatest landmark in the history of medicine. His *Exercitatio Anatomica de Motu Cordis et Sanguinis* was published in the year 1628. It met with early recognition in many countries, but its influence upon the practice of medicine was only gradual. Harvey himself is said not to have excelled as a practitioner, but the facts that he was physician to Charles I, and that he was chosen as Lumleian Lecturer at the Royal College of Physicians, show that he was held in high esteem. One of his aphorisms may be quoted: "I am of opinion that our first duty is to enquire whether a thing be or be not, before asking wherefore it is." If this maxim were always faithfully observed a great many controversies would be stillborn.

The seventeenth century, prior to the advent of Sydenham, was an unhappy period in the history of medicine. A vivid light is thrown upon it in the comedies of Molière. It was an age of dogmatism, of slavish adherence to rules, of neglect of clinical observation, and of drastic therapeutics, based mainly on methods of elimination. Pedauntry, routine, blind subservience to authority, reigned supreme. Blood-letting was practised to a frightful extent. Purgation, scarification, clysters, and other severe methods were in vogue. There was a rage for antimony, especially in France, where the drug was held to have cured the young King Louis XIV of a fever. Medical conversation was larded with tags of Latin. The following specimen is given of the medical learning of the day. Why does opium produce sleep?

Quia est in eo  
Virtus dormitiva  
Cujus est natura  
Sensus assoupire.

Medicine needed a reformer, and it found one in Thomas Sydenham, who earned the title of the British Hippocrates. Few men in any age have been more fully imbued with the Hippocratic temper. In his insight and sagacity, in his reliance upon clinical observation and practical experience, in his freedom from prejudice and erroneous theories, in the simplicity and thoroughness of his methods of treatment, he was a true follower of the great Greek. He achieved great fame both in his own country and abroad. Boerhaave, the famous physician of Leyden, never mentioned him without lifting his hat, and saluted him as "*Angliae lumen, artis Phoebum, veram Hippocratici viri speciem*." Sydenham wrote on many subjects—fevers, gout, chorea, phthisis, hysteria, pneumonia, dysentery, malaria. His account of chorea was so perfect that we still speak of Sydenham's chorea. He was the first to distinguish measles and scarlatina. His account of hysteria was long held as a classic. It is interesting to recall that he thought hysteria the commonest of all diseases, and held that few women are wholly free from it. He suffered much from gout, of which he has left an excellent description. He believed that it was the only disease which included in its victims more wise men than fools. In his famous work *Methodus Curandi Febres* he says: "Fever is nature's engine which she brings into the field to remove her enemy; or her handmaid either for evacuating the impurities of the blood, or for reducing it to a new state." Are we quite sure even yet how far pyrexia is an irritative reaction or part of Nature's defensive mechanisms? We know it can run to perilous excess, but routine antipyresis may run the risk of defeating Nature's efforts at elimination and control. The subject is one to reflect over. Sydenham was a stout upholder of the doctrine of the *vis medicatrix naturae*. He writes:

"As far as I am capable of a judgment, the dictates of reason are as follows, namely, that a disease, however much its cause may be adverse to the human body, is nothing more than an effort of nature, who strives with might and main to restore the health of the patient by the elimination of the morbid matter."

He held that some diseases "are engendered through occult and inexplicable changes in the atmosphere." We are familiar with waves of both ill health and good health spreading over large areas without assignable cause. Perhaps Sydenham's notion is worthy of reconsideration. Perhaps to-day we attach too little importance to cosmic and telluric conditions. Sydenham held that impurities

A woman, aged 29, had an attack of encephalitis in September, 1920, with an abrupt onset of headache, vomiting, and diplopia. In October, 1920, she showed a divergent squint in both eyes with paresis of both internal recti. In November, 1920, right ptosis was present, as well as the paresis of the internal recti in December, 1920; this ptosis was still more marked. At the end of December, 1920,

The reason for that is that the scientists are not sure if the blood vessels are really damaged or if it is just a picture of a damaged vessel.

in the air were one of the main causes of phthisis—an anticipation of modern thought. He laid much stress upon diet in the treatment of disease, made a large use of diluents, recommended plenty of fluid in fevers, popularized the use of Peruvian bark in ague and iron in chlorosis, advised plenty of fresh air in sick-rooms, and thought horseback exercise valuable both in nervous affections and in phthisis. Like the Greek physicians, he urged the importance of studying the patient's constitution and avoiding routine treatment.

Sydenham's writings are full of pithy axioms and aphorisms—for example: "Experientia magistra doctorum"; "Qui mundificat bene, bene sanat"; "Lachrymae—certissima signa morbillorum." "Nevertheless, I have always thought it a greater happiness to discover a certain remedy for even the slightest disease than to accumulate the largest fortune, and whoever compasses the former I esteem not only happier but wiser and better too." Sydenham believed much in common sense. His favourite authors were Hippocrates, Cicero, Bacon, and Cervantes. Sir Richard Blackhouse, who had commenced the study of medicine, once asked Sydenham what book he would recommend. His reply was, "Read *Don Quixote*. It is a very good book. I read it still."

With Sydenham I may fairly conclude these burrowings in the medical lore of past ages. We began with Hippocrates; we conclude with his English successor. Between Hippocrates and Sydenham what a vast vista of human history—a period of just over two thousand years! During that long period the healing art has seen many vicissitudes—now advancing, conquering, again coming to a standstill, or undergoing grievous relapse. But it is significant for us that the English Hippocrates found it to his advantage to have at his elbow the works of his great forerunner. We might with profit follow his example. The past is not dead—it lives in us, in our lives, and in our work. We do not forget that in the three hundred years which separate us from the birth of Sydenham medicine has made a greater advance than in all the previous ages. But, as Rudyard Kipling says, "that is another story."

## THE DIAGNOSIS OF SMALL-POX AND CHICKEN-POX: A CONTRAST.

BY

G. R. PAINTON, M.R.C.S., L.R.C.P., D.P.H.,  
LATE ACTING M.O.H. GLOUCESTER CITY.

(With Special Plate.)

The photographs reproduced on the special plate by which this paper is illustrated exemplify the fallacy of placing much reliance upon the severity of the rash in making a differential diagnosis between chicken-pox and small-pox. Figs. 1, 2, 3, and 4 are from a case of chicken-pox; Figs. 5 and 6 from a case of mild discrete small-pox. The ratio of severity so far as the rash is concerned is the opposite to what is taught to students of medicine and is still assumed by many members of our profession—namely, that small-pox is characterized by a profuse rash, and that chicken-pox is perhaps the mildest and most negligible of all the exanthemata. Figs. 1, 2, 3, and 4 show the rash twenty-four hours old in girl aged 11; she had no prodromal symptoms; the type of rash was very superficial and the fluid in the vesicles was quite clear (glass-pox). The crenated edge of some of the vesicles can be seen in the back view. The distribution is centripetal. Figs. 3 and 4 (from the same case) show vesicles on the palms and soles, but still of the superficial type; such a condition is common in chicken-pox. Figs. 5 and 6 are of an unvaccinated boy aged 6, suffering from a mild form of discrete small-pox. The prodromal symptoms were headache, slight sickness, and pains in the limbs; the rash appeared on the fifth day. The rash, it will be noted, is centrifugal and deeper than in chicken-pox, and the pocks are circular with a central depression.

It should not be difficult to understand that doubt may exist in the mind of a medical officer when called on to make a diagnosis of small-pox in such a case as this, perhaps the first to occur in his experience, or even, with previous experi-

ence, the first case in a community hitherto free from this disease, and to report his finding to the health authority.

A correct diagnosis can and should be made, and in typical cases, even when very mild, it is simple enough. The sheet anchors of differential diagnosis are:

1. The distribution of the rash.
2. The prodromal history.
3. The characteristics of the rash.

I would like, however, to stress the possibility that these points are not always obvious and clear-cut.

### Distribution.

Border-line cases occur sometimes, but fortunately rarely, and in these a count of lesions leads to no conclusion as to whether the rash is centrifugal or centripetal, and every mathematical maxim fails.

### Prodromal Symptoms.

No one symptom is so consistently obvious as to constitute *per se* a specific point of diagnosis. The length of the prodromal period—that is, three to four days' illness in small-pox before the appearance of the rash—is of great importance, but very careful inquiry is often necessary, both as regards the prodromal beginnings and the first appearance of the rash, to elicit information substantiating this length of period.

The symptoms of themselves may vary in severity between one extreme and another in small-pox, and the eruption which follows does not appear to have any definite relation to the degree of their severity. Headache, a most constant feature in mild small-pox, may be described in every degree from "very severe" with delirium to a feeling of "giddiness" only. Pains in the back and limbs may vary from the excruciating type to a "feeling of tiredness" or "heaviness in the legs," enough to make the patient prefer to "lie up" rather than to "keep about." Vomiting may vary between persistent retching and "just wanting to be sick." The temperature may be high or normal. Prostration may be severe or absent.

Just before the appearance of the rash the prodromal symptoms of small-pox lessen to a very marked extent and the temperature when high may fall, so that the patient "feels better," and may return to work, or to school, as the case may be.

Chicken-pox sometimes, especially in older people, may be preceded by fairly severe symptoms of headache, etc., lasting for a few days. In chicken-pox, however, this prodromal stage is usually of shorter duration and the symptoms run on and overlap the eruption; the temperature is often highest on the second or third day of the rash.

### Character of the Rash.

A typical chicken-pox rash and a typical small-pox rash are easily distinguished, but a chicken-pox rash may be severe and very pustular, and small-pox lesions may be of an abortive type; even when not abortive they may be more superficial and less markedly round than usual and may have the appearance of successive crops on successive days. The rash in chicken-pox is, however, more cuticular (glass-pox), matures more rapidly, has a more oval shape with a more crenated edge and with deeper areolae tending to run in the creases of the skin and producing an exaggeration of the ovoid appearance or giving a markedly stellate shape. On the other hand, small-pox lesions are deeper, less rapidly maturing, round, with a narrow round areola, and later on a circular central umbilication.

Confusion is sometimes caused by a resemblance of small-pox lesions to the polymorphism seen in chicken-pox, due to deeper lesions or those under denser tissue taking longer to mature, and to the fact that some small-pox lesions abort in an early stage. Then again, in chicken-pox spurious umbilication may occur, but the vesicle is more convincingly monolocular, small-pox vesicles being usually multilocular. Again, two or more small-pox lesions may run together and produce a crenated edge and an oval appearance. To complicate things a little more, post-vaccinal rashes occur more commonly than is supposed. Prodromal rashes, secondary rises of temperature, particular smells, predilection to come out more profusely at places of friction, are among other points to be considered but are inconstant.

FIG. 1.

FIG. 2.

FIG. 4.

FIG. 3.

FIGS. 1 TO 4.—A case of chikokun-pox. The superficiality of the lesions is well shown on the palm of the hand and sole of foot.

His experience had been that, in this case, involuntary movements as a whole tended to disappear after a lapse of months or years. He would, however, except tremor of the Parkinsonian type, which appeared to persist indefinitely. With regard to the prognosis, it was important to discover if possible what was the limit of the latent interval which might elapse between the original illness and sequelae. He had seen one case in which the Parkinsonian syndrome developed after a lapse of two and a half years. During this period, however, the patient could never be said to have made a complete recovery. In the original illness lethergy was the main symptom. Later insomnia and nocturnal restlessness (the patient was a boy of 15) became exceedingly prominent. The boy's character also showed signs of deterioration. His own impression was that if the patient in the original illness recovered his physical and mental health and maintained that recovery for a period of six months, he might be regarded as safe from further trouble. Finally, in discussing the symptomatology of this disease, he thought perhaps that they paid more than a fair share of attention to the involuntary movements. He called attention to the great variety of sensory disturbances of which these patients complained. The somatic pains had already been referred to by other speakers. Dr. Hinds Howell had mentioned that in one of his cases there occurred gasping Dr. Symonds had met with cases in which the patient had made movements of a similar nature, and had explained them as being due to a sensation of impeded respiration and association of which he had tried to rid himself by energetic sleep breathing. Other instances of that type had been mentioned, which impelled him to be constantly blowing and smiting, and a woman who, even in the early stages of her illness, complained chiefly of a sensation of fullness and tenderness in the rectum, for which she was constantly deponing and emptying her bowels were emptying normally and physically examination revealed no local cause. Symptoms of this nature were of particular interest in relation to similar complaints made by patients of the so-called neurotic type. They had to ask themselves whether there might not be a physical basis for such symptoms in minute lesions of the micro-sensory nervous centres.

Dr. H. J. Macgregor (London) said that a short clinical contribution to the discussion was difficult because of the wealth of clinical material offered by this disease. The discussion was on the sequelae of encephalitis lethargica, and how far were they justified in placing many of these cases under the heading of sequelae? Were they not, in many cases, dealing with a still active infection? Several of the cases he had seen recently after the onset of the disease during the nearly days of their illness. And again in some cases the symptoms had markedly altered during the so-called post-encephalitic stage. This was well shown in one of the cases which he described later. Economou found *post-mortem*, in a chronic case, quite recent patches of inflammation. So that both the clinical and pathological conditions were not far from what the active process might be expected to show. Further, they knew that a definite recovery or relapse had occurred in some patients.

FIG. 5.

FIG. 6.

FIG. 7.

group—those showing a similarity to the paralytic agnitions, and (b) those showing other miscellaneous symptoms. It was to a particular group from the latter three cases, each of which showed a condition closely allied to torticollis.

#### CASE 1.

A young woman, aged 28, had an attack of encephalitis in 1920, which marked downwards lasting several weeks, and ocular trouble followed shortly afterwards by the movements which she at present has. The movements consisted of an irregular spasmodic turning of the head to the right, with a slight forward and swinging movement of the right shoulder. Each spasm lasted not more than one or two seconds. Accompanying these head movements, were movements of extension and internal rotation of the upper limbs with wide separation and extension of the fingers. The extension movements of the left arm were sometimes replaced by a movement of flexion, with flexion of the fingers. The lower limbs were usually unaffected, though there were slow movements of them, as well as of the upper limbs, apart from the head movements. The movements of the extremities resembled those of torsion spasm, except that the movements were slow and unaccompanied by any spasmodic jerks. The lower limbs were usually unaffected, though there were slow movements of them, as well as of the upper limbs, apart from the head movements. The movements of the extremities resembled those of torsion spasm, except that the movements were slow and unaccompanied by any spasmodic jerks. The lower limbs were usually unaffected, though there were slow movements of them, as well as of the upper limbs, apart from the head movements. The movements of the extremities resembled those of torsion spasm, except that the movements were slow and unaccompanied by any spasmodic jerks.

#### CASE II.

A young woman, aged 31, about a year before had an illness which she called influenza and in which she was very drowsy for several days. This was followed by side-to-side movements of the head, more to the left than to the right. These movements continued up till the present time. The patient now had the head constantly inclined to the right with the chin very slightly turned to the left and the occiput approximated to the right shoulder, while this shoulder was slightly higher than the left. Side-to-side head movements of small amplitude were continually present while she was erect, but ceased in the recumbent position. While she was standing there was also a regular up and down movement of the whole body, at a rate of about 60 to the minute. Reflexes were normal.

A young man, aged 28, had an attack of encephalitis lethargica in 1921, followed by the paralytic agnitions picture. This state continued for many months, then his condition became that which was found on readmission to the National Hospital last year. The paralytic agnitions tremor, and his complaint was of head movements; they consisted of spasmodic forward movements of the head with elevation of the left shoulder and slight turning of the chin to the right. Associated with them were deep nasal inspirations. Reflexes were normal except for the left plantar which was extensor in type.

These cases were interesting not only from the point of view of the disease under discussion, but also on account of the light they might throw on other conditions. The symptoms following an encephalitis lethargica could be grouped into well known syndromes, yet the knowledge of these syndromes had allowed them to draw very few conclusions as to the pathology of this disease. They might look at the matter from the reverse side and ask themselves whether their study of encephalitis lethargica had allowed them to draw any conclusions with regard to the syndromes which occurred in consequence of it. As far as paralytic agnitions was concerned it had merely taught them that such a condition might have an infective origin. With regard to torticollis he submitted that it gave an additional ground for believing that some cases at least had their basis in an organic lesion of the brain. Dr. Macbride said that he was much indebted to Dr. James Collier for permission to quote the above mentioned cases.

Dr. W. A. Potts (Birmingham) said that the theory of temporary oedema in certain regions of the brain seemed to explain the rapid recovery which occurred in some cases. For instance, a young woman on the first day was only slightly ill, on the second she was in a state of stupor, not able to move, not speaking or taking food; on the fourth day she was up and dressed, and almost quite well. She recovered rapidly and had no sequelae. Dr. Hinds Howell's interesting group of cases prompted Dr. Potts to ask if psychological analysis had been tried, and also

## DISCUSSION ON

## THE PROGNOSIS OF PSYCHOSES OCCURRING

### DURING ADOLESCENCE.

#### OPENING PAPER

BY

D. K. HENDERSON, M.D.,

Physician Superintendent, Glasgow Royal Mental Hospital, Gartnavel.

The prognosis of mental disorders occurring at the adolescent period is a topic of tremendous magnitude and reaching importance. It is only limited by the application of the word "mental," and in order to limit the purposes of this paper, and in order to limit the scope and keep the discussion within more or less well defined limits, I have made an attempt to formulate my conclusions in regard to those types of mental disorder which ordinarily are termed the dementia praecox group. While this is so, and although this paper deals essentially with hospital cases, yet I trust my remarks may be as even more applicable to potential cases than to completely dissociated ones. I do not know of any more tragic event than the occurrence of a mental disorder at the time of life the period of childhood training cases, and life with its possibilities seems to be opening up. Until the development of mental symptoms the boy or girl affected have shown a capacity for work, and an intelligent forward to a bright and successful future, and in the meantime these symptoms, which in other circumstances might have given cause for uneasiness, are all too quickly glossed over and explained away. It thus happens that the early preventive period becomes lost. A person familiar with colleagues who up to a point have

It is the weighing up of all points that produces the convinced diagnosis, and it is this diagnosis in an early case of mild small-pox that is at the same time both essential and difficult. A missed case (for the doctor is not always sent for) or an error in diagnosis is the usual and regretted beginning of epidemics, mild or severe.

There is no dividing line to be plainly seen between small-pox *sine eruptione*; mild small-pox, with one, two, ten, twenty, or a hundred lesions; severe, discrete, confluent small-pox, and the haemorrhagic forms of this disease.

The conjecture that there is a separate and distinct disease—alastrim—must be rejected. Leake and Force of the United States Public Health Service made certain experiments on rats and monkeys with material from cases of so-called alastrim in the West Indies. They found<sup>1</sup> that in monkeys a vesico-papular eruption was produced by inoculation of crusts or the contents of vesicles from such patients and that the animals were protected against re-inoculation with the virus or with vaccinia. Rats inoculated with alastrim did not develop an eruption, but became almost completely immune to vaccine virus. When intracutaneous inoculation is made with small-pox crusts, alastrim material, and vaccine virus in rats in the manner used in the Schick test for diphtheria, a reaction occurs. Rats previously inoculated with vaccine virus gave an intracutaneous reaction to small-pox crusts, alastrim material, and vaccine virus, but remained negative to chicken-pox crusts. They conclude that definite immunity to vaccinia is produced by previous inoculation with alastrim and that this affords additional evidence of the essential identity of alastrim with small-pox.

Taking an average of small-pox fatality for 276 cities in the United States of America and Canada, the rate has increased from 0.6 per cent. in 1920 to 5 per cent. in 1922, and at the present moment it would be unwise to presume that the mild type of small-pox as seen in Gloucester and the North of England will not revert in the future to the more fatal form of the disease.

I have endeavoured in this short article to bring out the fact that a definite diagnosis between these two diseases is at times extremely difficult. In the recent Gloucester epidemic the two diseases existed side by side in the same family; in such an instance a case of chicken-pox was admitted to hospital as one of small-pox. The patient, on recovery, was discharged from hospital, and a few days later passed through a typical prodromal history and developed a typical and profuse small-pox rash! The converse has also happened, a small-pox patient on discharge from hospital developing a typical chicken-pox eruption within a month of discharge.

Administrative measures for dealing with an epidemic of mild small-pox must at present remain the same as if we were dealing with the virulent type of the disease. One matter of paramount importance which should never be omitted where small-pox threatens is the provision of an observation ward where cases of doubt can be isolated. As stated before, a correct diagnosis can and should be made, and the number of cases for observation should be small.

## CLINICAL NOTES OF FIFTY CASES OF SMALL-POX (1923).

BY

G. F. RIGDEN, M.C., M.B., B.S.,

MEDICAL OFFICER, GREENBOTTOM SMALL-POX HOSPITAL, GLOUCESTERSHIRE.

IN the following notes of 50 consecutive cases occurring in West Gloucestershire, the main consideration has been to show on which of the classical diagnostic points reliance may be placed in the light of present experience, and especially to emphasize those points in which the current type of the disease differs from the classical. The cases are the first fifty admitted to the West Gloucestershire Small-pox Hospital during the present epidemic, and occurred

between May and October, 1923. The first and several subsequent cases were imported from Gloucester; the remainder were contacts of earlier cases.

Of the 50 cases, 27 were males, 23 females; the youngest was 2 years of age; 2 belonged to the age-group 2 to 5 years, 9 to the group 5 to 10 years, 13 to group 10 to 15, 9 to group 15 to 20, 9 to group 20 to 30, and 8 were from 47 to 55 years. Forty-two were unvaccinated; the remaining 8 had been vaccinated in infancy and never re-vaccinated; the youngest vaccinated case was 23, and the next youngest 47 years old, so that none of the patients had been vaccinated within twenty-three years and only one within forty-seven years.

In type the cases were fairly clearly divided into a mild type (36 cases) and a semiconfluent type (14 cases). The mild type had a less severe prodromal illness, fewer spots, and a quicker convalescence. Some of these were very mild indeed, the prodromal illness being negligible and the rash confined to a very few spots on the face, wrists, or ankles. There can be no doubt that several cases of this kind passed unrecognized, so keeping up the epidemic; it was established beyond doubt that the mildest cases could hand on the disease in semiconfluent form to contacts. Previous vaccination did not appear to affect the type—of the 8 vaccinated cases 6 being of the mild and 2 of the semiconfluent type.

The semiconfluent type of case had a more severe prodromal illness, being in every case confined to bed, a profuse rash consisting of many hundreds of spots so that the features in the worst cases were quite unrecognizable, and usually a longer convalescence. In none of these cases was the constitutional disturbance at all so severe as one would have expected from so many pustulating vesicles.

One of the patients had been successfully vaccinated in the incubation period, four good vesicles forming; his subsequent illness was in no way different from that of the other mild cases. The remaining 49 were vaccinated on admission to hospital to confirm the diagnosis; immunity to vaccinia was complete in every case.

**Incubation Period.**—As a student, the writer was once asked by his chief on what day of the week the rash of small-pox most often appeared; the correct answer was "Sunday"—that is, fifteen days from the most likely day of infection under prevailing social conditions. Although difficult to establish with accuracy, this appears to have been about the interval in these cases.

**Prodromal Period.**—The onset being in the great majority of cases quite definite, it has been possible to define the length of this period with more accuracy and the result has failed altogether to confirm the four days universally described in textbooks. In three cases it was impossible to determine accurately the commencement of the disease; of the remaining 47 cases the rash appeared once on the second day, three times on the third day, twelve times on the fourth day, fourteen times on the fifth day, twelve times on the sixth day, four times on the seventh day, and once on the eighth day; in a certain number of cases, however, medical advice was not sought until the rash was well out, and it is possible that the rash may occasionally have been present a day before it was recognized by the patient's friends.

In the great majority of cases the prodromal illness was first diagnosed as a "chill" or "influenza"; two patients who had had pneumonia before complained of "pain like pneumonia but a little lower down"; one case was diagnosed "lumbago." Only four times was lumbar pain at all prominent, headache being the pain usually complained of. Initial vomiting occurred in 3 cases; there was no case of convulsions and no prodromal rash. Those cases which were under observation during this period had usually a temperature of from 100° to 103° F., which fell to normal when the rash appeared, and in quite a number of instances on the day previous to the rash. It was impossible to establish any relationship between the duration of this period and the severity of the subsequent disease.

The nature and distribution of the rash was very consistent in all cases, differing only in quantity. Appearing

always first on the face, it followed in a few hours on the arms and legs, with a few spots on the back; the chest and abdomen were nearly free, in many mild cases absolutely free, the picture so formed being very striking in its contrast to varicella; on the limbs the rash was always centrifugal. There was no succession of crops as in varicella, all the spots in a given part of the body being of the same age. The individual spots were in the deeper layers of the skin as opposed to the superficial vesicles of varicella, and passed through the classical stages on the face in about ten days; in the limbs much longer was required, unbroken pustules being often present after the face was clear; the last to clear up were always round the ankles and on the soles of the feet. A few of the largest spots were punctured and found to be unilocular; umbilication was frequent but not universal. So uniform was the rash in its essential features as regards both its nature and distribution that the diagnosis rarely gave any anxiety once the rash was well out.

Secondary rise of temperature occurred in all but one of the semiconfluent cases and in 10 of the mild cases—twenty-three times in all. It was invariably septic in type, and while it lasted patients always felt worse than during the early days of the rash, though usually not so ill as in the prodromal period. It commenced on the third or fourth day of the rash and lasted for one day only in 7 cases, for two days in 4 cases, for three days in 2 cases, for four days in 7 cases, and for five, six, and nine days in one case each. In only 10 cases did it exceed 100°, the highest recorded being 101.6°.

Conjunctivitis occurred during pustulation in 6 cases and appeared to be caused by pustules on the eyelids; arthritis of the knee occurred once during convalescence, in a man of 55 not previously subject to "rheumatism." There were no other complications; one case each of imperfectly compensated mitral disease and of six months' pregnancy were unaffected, both being cases of "mild" type.

Treatment was symptomatic only. From the period of scabbing onwards all patients were liberally treated with olive oil and hot baths; the nursing staff as well as the author were convinced that this materially shortened convalescence.

**Duration of Infectivity.**—After the scab had fallen off a purple scar remained, at first slightly raised; around its edge was often attached some dry skin, the remaining circumferential part of the skin originally covering the vesicle. Until this had disappeared from all the spots the patient was regarded as still infectious. The last part to clear was invariably the ankles and soles of the feet, and the process was completed within three weeks of the appearance of the rash in 23 cases; in 20 cases infection persisted to the fourth week, in 3 cases to the fifth, in 3 cases to the sixth, and once to the seventh week. Liberal applications of olive oil and hot baths materially assisted the removal of this dry skin; premature picking off of the scabs, on the other hand, delayed the process. The patients were discharged immediately at the end of this period and there were no "return cases"; the scars faded gradually in the course of several weeks after discharge and do not appear to have left any pitting.

#### Conclusions.

1. It is impossible to diagnose the present type of small-pox before the appearance of the rash.
2. Fall of temperature without appearance of rash in a suspected case does not immediately preclude the possibility of small-pox; nor does the non-appearance of rash on the fourth day.
3. The centrifugal distribution of the rash and its comparative absence on the chest, its depth in the skin, and the absence of successive crops are reliable guides in the differentiation from chicken-pox.
4. Successful vaccination performed after the disease has appeared excludes small-pox, but successful vaccination during the incubation period has no diagnostic value.
5. The protective value of recent vaccination is once more abundantly confirmed.

## TWO CASES OF INTRA-ABDOMINAL HERNIA.

BY

E. ROCK CARLING, M.B., F.R.C.S.,

SURGEON TO THE WESTMINSTER HOSPITAL,

AND

E. MERVYN JONES, M.R.C.S.,

LATE HOUSE-SURGEON TO THE WESTMINSTER HOSPITAL.

### I.—HERNIA INTO THE INTERSIGMOID FOSSA.

THE intersigmoid fossa has been described by Treitz,<sup>1</sup> Waldoyer,<sup>2</sup> and Treves<sup>3</sup>; the mechanism of its formation, suggested by Toldt,<sup>4</sup> was confirmed by Moynihan.<sup>5</sup> Records of hernia into the fossa are very rare. Bryant,<sup>6</sup> Eve,<sup>7</sup> Eccles,<sup>8</sup> Coley,<sup>9</sup> Murphy,<sup>10</sup> Barnard,<sup>11</sup> Black,<sup>12</sup> and Marsh<sup>13</sup> relate or refer to cases, but, in some of these, particulars are wanting. There are no doubt others, overlooked, but the references have not been verified. Most of the cases were seen as "intestinal obstruction," without previous history of abdominal disorder; in one or two there was a history of attacks of constipation with left-sided abdominal pain.

The patient, aged 47, a man of fine physique, at the end of a journey from the Continent, was seized with sudden abdominal pain, at first in the right iliac region; later it spread across the whole lower abdomen, and he vomited. A few hours later he was seen by Dr. Cumming Grant, who found him collapsed. He had had an urgent desire for stool, which persisted although the bowels did not act, nor was flatus passed. At first he had micturated easily, but now had difficulty and pain. Vomiting recurred.

When seen by us the whole abdomen was distended, rigid, and tender, the greatest tenderness being in the left iliac fossa; there was no recognizable hyperaesthesia, nor could any "lump" be felt; the whole abdomen was slightly tympanitic. On rectal examination oedema of the mucosa was found high up and general fullness of the recto-vesical pouch, but no "lump" could be felt.

The patient himself, although he had had no previous attack, felt sure he was suffering from appendicitis. Without dismissing that possibility, the abdomen was opened as for intestinal obstruction. On entering the pelvis the hand at once encountered an indefinite fixed fullness on the left posterior wall. Coils of small intestine of unequal calibre were seen passing towards this region, but not until the sigmoid had been drawn up and over to the right was the mass revealed. It proved to be incarcerated small gut behind or between the layers of the sigmoid mesocolon. The whole sigmoid and upper part of the rectum were markedly oedematous. The opening looked downwards and to the right. The intestine, 8 to 10 inches, was easily withdrawn and was clearly viable. The pouch admitted three fingers to their whole extent, and was directed upwards and to the left. The margin of the opening was rounded though oedematous, and the sigmoid artery, arching in the upper edge, coursed down the left rim. The ureter was not identified; the bifurcation of the iliac was below and slightly to the right. It was thought inadvisable to attempt any suturing of the opening; the sigmoid was turned down and its outer edge stitched to the abdominal wall as far down and to the left as possible.

Recovery was without incident.

### II.—HERNIA THROUGH A DEFECT IN THE MESENTERY.

The anatomy of the aperture in the following case corresponds exactly with the description given by Treves.<sup>14</sup> Possibly the type may not be very rare, but records are certainly scarce. Howard Marsh<sup>15</sup> described one in 1888, and Barnard<sup>16</sup> mentions two, but both of them were traumatic. This case differed entirely from the two of deficiency of the last part of the mesentery recorded by Armstrong,<sup>17</sup> in that the terminal part of the ileum was quite free from attachment to the abdominal wall. There was no history of trauma in this instance. It seems probable that the attacks of pain were due to incarceration of a loop of gut.

A single woman, aged 31, one of twins, a patient of Dr. Garden, was admitted to the Westminster Hospital in May, 1923, having had attacks of "appendicitis." The first attack, in February, 1923, was

accompanied by abdominal pain, a dull aching across the belly above the umbilicus, shooting down into the right iliac fossa and right loin. There was nausea but no vomiting. Micturition was normal; the attack lasted twenty-four hours. There were recurrent attacks in March and April; the former lasted two days; in the latter, which coincided with the onset of a menstrual period, the pain was very severe, and continued intermittently until admission on May 19th. The diagnosis was "appendicitis." The patient was said to have suffered from "gastric ulceration" in 1913 and "gastric influenza" in 1921.

Mesenteric Defect. A. Ileo-colic artery.  
B. Branches of superior mesenteric.  
C. Edge of gap held widely open.  
D. "Free" part of ileum.

In the right iliac region, tenderness over the caecum on deep palpation and high up on the right wall of the rectum; there was slight but definite hyperaesthesia in the right lower quadrant of the abdominal wall. The temperature was 93.6°, pulse 90.

At operation the appendix was found, 5 inches long, with a definite kink; the superficial vessels were injected, but there were no adhesions. On further examination a defect was found in the mesentery of the terminal part of the ileum. The slit-like aperture was about 5 inches long; the edges could be freely separated, and then allowed passage to all the fingers and palm; the margins were firm, smooth, slightly thickened, and opaque. Surrounding the defect was an arcade between the ileo-colic artery and a terminal branch of the superior mesenteric. A loop of small intestine, 6 to 8 inches long, passed with its mesentery through the opening; it was withdrawn with but little difficulty. There were no signs of previous inflammation in the region. The margins of the aperture were approximated by a continuous suture. Recovery was without incident.

#### DISCUSSION ON THE SEQUELAE OF LETHARGIC ENCEPHALITIS.

##### OPENING PAPER

BY

E. FARQUHAR BUZZARD, M.A., M.D. Oxon., F.R.C.P.,  
Physician, St. Thomas's Hospital.

ALTHOUGH only about five years have elapsed since lethargic encephalitis was first recognized in this country, we have become so familiar with the ravages caused by this disease that the consideration of its sequelae can hardly fail to prove interesting and instructive. In opening this discussion it is perhaps desirable to define as far as possible the meaning of the term "sequelae" as applied to encephalitis. This in itself is no easy task because the active phase of the disease has little uniformity in regard to its features, its severity, or its length. It is often difficult, therefore, to separate the primary results of the inflammatory process from signs and symptoms which appear at a time when the inflammation of the cerebral tissues may be presumed to have died away.

For the purpose of this discussion it may be convenient to regard as sequelae (1) those disorders of function which appear for the first time after the disease has spent itself, and (2) progressive alterations in defects of function which have been left as more or less permanent legacies of the disease. A good example of the first category is epilepsy and of the second is the progressive intensification of the Parkinsonian syndrome already inaugurated during the acute phase. The acceptance of these two classes of sequelae can be justified on the plea that the pathological process underlying either is sufficiently obscure to warrant our closest inspection.

The interest of our discussion is likely to lie in three directions. In the first place we shall be glad to learn from one another of the varieties of sequelae which have been met with, their relative frequency and their relationship to the features of the primary disease. Further light on this subject would be invaluable in regard to the question of prognosis. In the second place we can exchange views as

to the nature of the changes in the cerebro-spinal system responsible for those defects of function which we include in our definition of "sequelae." This is a pathological problem of fundamental importance. Finally, we shall welcome the opportunity of acquiring any information which may be available in respect to the prevention or cure of these distressing disabilities.

It is more than probable that our list of sequelae, already long, will be added to from time to time, seeing that every function of the central nervous system may be affected by the disease. I shall be content to draw your attention to those phenomena which are common and to those which may have some special interest.

#### Mental Sequelae.

When the relatives of a patient suffering from encephalitis are told that his brain is inflamed their first concern is the mental state of the victim in the event of his surviving the disease. An answer to this question must always be carefully guarded, as experience has taught us that encephalitis may leave in its train many defects of function on the part of the higher centres varying greatly both in regard to severity and duration. From a practical point of view it is well to warn relatives, and often the patient himself during convalescence, that, however slight and transient the active phase of this disease, it is apt to leave the nervous system very much below par for many months and sometimes for years.

In simple cases the patient may complain only of those symptoms which we associate with the term "nervous exhaustion" and which include lack of energy, of concentration and decision, depression, restlessness, and insomnia. Unless the warning note is sounded children are sent back to school and adults return to business long before they are fit for work, and sometimes with disastrous results. Knowing what we do of the pathology of the disease, it is folly to expect such a delicate piece of machinery as the human brain to recover its normal functions unless it is given ample time for rest and recreation.

Fortunately mental changes are not more severe than this in the majority of cases. But there are other patients in whom the disease initiates a complete alteration of mental capacity or a revolutionary change in behaviour and adaptation.

A woman developed an acute attack of delusional insanity lasting for a fortnight about two months after recovering from encephalitis. Another woman displayed for many months a mental attitude which was quite at variance with her normal personality. She was boastful, conceited, lacking in reserve, and loquacious. Curiously enough she recognized and deplored her tendencies, although unable to control them. Perhaps the most common and most tragic cases of mental deterioration are seen amongst children.

THE BRITISH  
MEDICAL JOURNAL

that the only thing that kept her from destroying herself was the knowledge that when she died she would go to a worse hell than the one she lived in. She asked, "Did you know what I mean?" He replied, "Yes."

Jackpot, and placed in the deepest gangue due to a straight-jacket condition, or great emotional depression, there were no psychotic symptoms; there was no evidence of mania or melancholia. In fact, the expressed ideas which she expressed were more less in harmony with her mood. Perhaps also one might emphasize the fact that when she was 17 or 18 years old she had a fight with a boy who also belonged to the set of the Plymouth Brethren. She stated how she had despised him because she had fought seen in his company." During the course of eight or nine weeks this patient was able to readjust herself, and has resumed work in the post-office.

A case such as this again brings forward very strongly the biological viewpoint, and makes one think in terms of a life-history, and much less in terms of symptomatology. Indeed, if one had to think of the symptoms in such a case as a depressed condition with both suicidal impulses and ideas in regard to her sex and life and her misdeeds in general, occurring in a setting of a relationship—the general tendency would very probably be regarded as type of illness as one or the other, a very guarded course. If, however, one thinks of it in terms of etiology and reaction to actual difficulties, then one comes to realize that here one was dealing with a girl who had shown capabilities of a very exceptional degree, which had been a leader among her friends, and had been beyond the average level of reaction characterized by various psychotic symptoms which have dealt with, to, of, the, been considered in institutions, like, and not even mentioned by her mother's treatment of her. I would therefore again emphasize in connection with this case that our prognostic is should not, but should be put on a par with the etiological factors and the life-history.

In contrast to the above cases I would like, very briefly, to report three further cases, which bring into prominence the consideration of exogenous factors as opposed to

[illegible]

When her mother knew she became angry with her, and did not know such things, she would try to express her feelings by writing letters to her, and by herself punishing her. On account of all this she felt that there was no possible hope for her, that there was not a God.

Bright, well behaved individuals before the illness, subsequently lose most of their moral sense and become quite ungovernable either at home or at school. A particular group of them display somnolence during the day and restless uncontrollable excitement at night. A few children show a progressive mental deterioration, sometimes, but not always, associated with epilepsy. Severe paroxysmal headaches are not uncommon in patients who continue to exhibit attacks of drowsiness and a progressive impairment of intelligence.

#### *Involuntary Movements.*

Much has been written about involuntary movements in encephalitis. They may occur during the acute phase or may make their first appearance weeks or months later. They may involve any muscular territory and vary from rhythmical twitches of one or two muscles to complicated and more or less co-ordinated movements of a limb. Speaking generally, these muscular spasms occur chiefly when the patient is at rest and unoccupied, voluntary activity apparently being able to inhibit temporarily the involuntary disorderliness. I need not detain you with any further description of these movements, but should like to refer to one case in which the muscular spasms had features of interest.

In December, 1920, I saw a man, 45 years of age, whose illness had commenced three weeks earlier with intense pain and hyperaesthesia over the right side of the scalp. This was followed a few days later by fever, drowsiness, diplopia, and left-sided ptosis. When I saw him his temperature was 102°, he was difficult to rouse, and when roused quite disorientated. His pupils were small and sluggish in their reaction to light. Ptosis was more marked on the left side. He displayed clonic contractions of various muscles, particularly the left external oblique, the right pectoral, and the flexors of the fingers of both hands. The abdominal reflexes were absent, jerks present, right plantar response extensor, left flexor. He recovered from the acute phase of his illness in a few weeks and in the latter part of March, 1921, came to see me at my house. He then felt well in himself, but complained of pain on the radial side of the right arm and along the ulnar border of the left. On examination his pupils responded badly to accommodation and power of convergence was defective. The right face and arm were slightly weaker than the left. When stripped he displayed rhythmical contractions of the right deltoid, pectoral, latissimus dorsi, biceps and pronator radii teres and of the left pectoral and latissimus dorsi. The number of muscles involved varied with the position of the patient. Most were in action when lying relaxed on the couch, fewest when upright and walking about. The muscular contractions were quite regular and careful observation showed that their frequency corresponded to the pulse rate—about 72 to the minute. Three months later the spasms were much diminished in severity and in distribution, but were still regular and in time relationship with the heart beat. As far as I know this relationship has not been recorded, although Dr. A. J. Hall, in his interesting Lumleian lectures, refers to the fact that involuntary movements synchronizing with respiration have been observed.

More information is required in regard to the duration of these involuntary movements. I have seen them disappear in a few months, and I have seen them last five years, but as far as my experience goes the general tendency is in the direction of improvement as time goes on.

#### *The Parkinsonian Syndrome.*

This is one of the commonest sequelae of encephalitis. It may develop in an intense form early in the disease, gradually become less marked, and never show any signs of progress. The first case of this kind was one which I reported in 1918. The patient was then completely disabled but he gradually recovered sufficiently to get back to his work, which he is still following in spite of the fact that he is 59 years of age. Not unnaturally one was at first inclined to regard the prognosis in these cases as favourable. Further experience has shown, however, that this is not by any means the invariable rule, and most of us must have seen patients whose symptoms and physical signs have become

steadily intensified and whose disablement has become gradually more and more complete. On the other hand, there appears to be a middle group of cases in which the amount of disability tends after a while to become stationary, especially if the conditions of life are favourable. Youth does not seem to be a factor of much advantage in this relationship as my younger patients have certainly not done better than their seniors.

#### *Respiratory Disorders.*

Various disorders in the nervous mechanism of respiration have been recorded in the literature of encephalitis. One of my patients, a young subject with a progressive Parkinsonian syndrome, complained of shortness of breath which came on in attacks for no apparent reason. Under observation it appeared to me that from time to time involuntary respiration was replaced by voluntary and exaggerated breathing, but whether this was induced by failure of the involuntary mechanism it was impossible to determine.

#### *Hiccup and Vomiting.*

Spasmodic contractions of the diaphragm giving rise to hiccup are frequent complications of encephalitis, and may persist as sequelae for many months after the acute illness. Not infrequently they recur at intervals when the patient is tired or under stress. Attacks of vomiting are much less common and may be unaccompanied by any feeling of nausea.

#### *Optic Neuritis.*

Slight papilloedema is not infrequent in severe cases during the height of the disease, but Foster Kennedy has drawn attention to the occasional occurrence of severe optic neuritis as a late symptom in convalescing patients. I have recently observed optic neuritis in a young woman who developed the complication when headache, drowsiness, and other symptoms were disappearing. It persisted for many weeks and was associated with paroxysms of transient amblyopia lasting for a few minutes. When last seen the patient was well in all other respects and the papilloedema was decreasing in intensity.

#### *Lethargy.*

In some cases lethargy may be regarded as a sequela, although there is little doubt that recrudescences of the active disease are sometimes responsible for its late appearance. I have seen several patients in whom lethargy has been a marked feature of the primary illness, who have made sufficiently good recoveries to allow of their taking up active life and who have still recurrent attacks of sleepiness, sometimes associated with headache. In this group there is nothing clinically to suggest a recrudescence of the cerebral inflammation, and I am inclined to think that the drowsiness has a mechanical basis—in other words, that the patients are suffering from a mild degree of hydrocephalus.

#### *The Pathogenesis of Sequelae.*

It must be conceded, I think, that all the sequelae of encephalitis cannot be attributed to recurrent attacks of cerebral inflammation, although there is experimental evidence to show that the tissues of the brain shelter an active virus for many months after the primary infection. Encephalitis lethargica is alone among the encephalitides in being characterized by the frequency and disabling effects of sequelae, and we must study the morbid anatomy of the disease to obtain any enlightenment as to their origin. It is now generally recognized that vascular accidents of great severity are more common in this form of encephalitis than in others, and many of the symptoms of the acute phase are produced by large haemorrhages, thromboses, and infarctions. Moreover, many observers have now recorded remarkable changes in the vessels of the brain, both in patients who have died during the acute stage and in others who have survived for many months. These changes have consisted of hyaline and calcareous degeneration of the vessel walls, chiefly involving the media and adventitia. It is obvious that such a process must interfere with the circulatory function of the vessels and sooner or later lead to defective nutrition of the tissues. This defect need not necessarily involve necrosis, but it is not unreasonable to

*Summary.*

paragraphs:

[illegible]

2. The formal differentiation of mental disorders occurring at the adolescent period into prognostic-diagnostic form of mental illness.

groups was a great advance on previous normal, and experience showed that differentiation on the basis of symptoms was unsafe.

visceral, and toxic side has met with a fair measure of success, and has stimulated research work, but there are still many cases which are outside the scope of such

4. The psychological conception is the most satisfying one, not only because it means an investigation of all

but also because it emphasizes the importance of working with whatever material is at hand, and of attempting to

5. Cases are reported which illustrate the above conception, and which show that the symptoms must always be considered in the light of the personality; other cases are

reported which emphasize the importance of attempting to differentiate between what is constitutional and what is exogenous.

6. A large proportion of the cases reviewed in this paper have shown well marked constitutional abnormalities, but there are many cases which, irrespective of constitutional defects, have significantly developed their outside interests

readjust; the prognosis in cases which have developed on an exogenous basis is infinitely better.

7. A complete recovery with good insight in cases of the dementia praecox reaction type is comparatively infrequent, but a social, as opposed to a medical, recovery

I think these last three cases which I have mentioned may be considered for the moment together. They all—as opposed to the cases already reported—show a severe and

to deal with they have become quiet and bidable, and have acquired a control over themselves and an adaptability towards the general situation which at first sight had

[illegible]

suppose that the blood supply to the nervous elements in territories where the vessels have undergone these changes is of an unreliable description. In this connexion I would remind you of the myoclonia with pulse rate rhythm to which reference has already been made. Moreover, it is comprehensible that tissues exposed to such a precarious source of nutrition should gradually lose their functional activity and so give rise to symptoms of progressive deterioration such as are recognized clinically in various ways.

It is difficult to avoid the conclusion that in encephalitis lethargica the virus has a specific affinity for vascular structures and that the resulting inflammation leads in some cases to temporary and in others to permanent interference with the blood supply of the tissues. If this is allowed it is not difficult to understand that certain areas of the brain may display a transient or progressive defect of function. Some observers have found that these vascular changes are more common and more pronounced in the basal ganglia than elsewhere, thus providing an explanation of the frequency with which the Parkinsonian picture is met with as a sequela. The problem of involuntary movements is not so easy as it involves the question whether they can be regarded as the product of irritative stimulation or of the unopposed activity of particular nervous centres. The solution of this problem cannot yet be stated with any degree of certainty, but I would remind you that an artificial anaemia of the cerebral cortex may give rise to involuntary clonic movements.

But there are other sequelae which cannot be attributed to vascular deficiencies. I have always regarded the lethargy of encephalitis with its remarkable fluctuations as impossible to understand except as the result of mechanical interference with the drainage of cerebro-spinal fluid from the third and lateral ventricles. In the active phase of the disease this may be explained by the inflammation and oedema of the tissues around the aqueduct of Sylvius. When lethargy appears as a recurrent sequela it may be justifiable to regard it as evidence of imperfect drainage of the ventricles due to scarring of the periaqueductal tissues. I am aware that there are other theories in regard to the origin of lethargy. The suggestion that it is a symptom of defective pituitary function and therefore associated with other evidences of hypopituitarism sometimes observed to follow encephalitis is interesting and worthy of consideration. Hitherto there has been no definite anatomical evidence that the hypophysis is often implicated.

Papilloedema, when it is accompanied by headache, vomiting, and other signs of increased intracranial pressure, does not require any special interpretation, but the late form of optic neuritis after signs of increased pressure have subsided, to which I have already referred, asks for a different explanation. Foster Kennedy suggests that local meningitic changes causing obstruction to the venous flux from the optic nerves may be the exciting cause of this condition, a suggestion which my own experience leads me to support.

Summarizing the later pathological changes resulting from encephalitis lethargica which may be responsible for the clinical sequelae, they appear to fall into three main categories: (1) Changes in the vessel walls with local impairment of blood supply to particular areas—especially in the basal ganglia; (2) a condition of chronic or intermittent hydrocephalus due to imperfect drainage of the ventricles; and (3) meningeal thickenings and occasionally perhaps loculated meningeal cysts interfering with venous drainage from the optic nerves.

#### Treatment.

We are still without any specific treatment for the acute disease and consequently unable to prevent the development of sequelae. Perhaps some of the mental disabilities already referred to may be avoided by the simple precaution of giving patients a sufficiently long and sufficiently protected convalescence. The same precaution may be effective in clearing up the residual symptoms and in rendering the appearance of physical sequelae less likely. The chief problem we have to face, however, is that of treating such serious disabilities as epilepsy, involuntary movements, and the distressing disability associated with the Parkinsonian syndrome. The treatment of post-encephalitic epilepsy

requires no special comment. In the main it is medicinal, but there are occasional cases in which the symptoms point to a definite focal lesion and in which the question of surgical intervention must be considered. I have seen meningeal cysts following encephalitis productive of Jacksonian epilepsy and cured by surgery.

So far it has been difficult to credit any therapeutic measure with success in preventing or diminishing involuntary movements. Perhaps tremor may be lessened by the exhibition of hyoscine, but my experience has not been very encouraging in this direction. Some observers have found that hyoscine and gelsemium are effective in mitigating the rigidity characteristic of the Parkinsonian patients and suppositories of belladonna have in one case at any rate produced dramatic if only temporary amelioration.

Speaking generally, I have had to rely chiefly on a combination of psychotherapy and physical re-education for any results in the way of alleviating distress and disability. If our conception of the pathological changes underlying the sequelae of encephalitis is correct, our only hope of success lies in helping Nature in its efforts to restore functional activity to damaged tissues.

#### DISCUSSION.

Dr. GEORGE RIDDOCH (London) considered it justifiable to limit the term "sequelae of encephalitis lethargica," as Dr. Buzzard had done, to two groups of disorders—namely, (1) those that had appeared first in the acute attack and persisted, and (2) those that had developed only after an interval of varying duration. But, at the same time, it was difficult to exclude subsequent acute attacks which not uncommonly occurred and were probably due to lighting up of the infection that had lain dormant in the nervous system. In illustration, the case of a girl of 16, at present a patient in the London Hospital, could be cited.

In the autumn of 1913 she had had a febrile illness in which profound lethargy and nocturnal delirium were prominent symptoms. She recovered in about a month. Eight weeks ago she again became ill with fever, diurnal sleepiness and nocturnal restlessness. Two weeks later diplopia developed followed after a week's interval by persistent hiccup that prevented her from sleeping. On admission to hospital two days later she was excited and mentally alert; she laughed immoderately and insisted that she felt perfectly well in spite of severe hiccups recurring at a rate of about 120 a minute. The other physical signs were as follows: photophobia, dilated pupils, which reacted fairly well on convergence, very poorly to light, and not at all on accommodation; weakness of both external recti with diplopia; slight right ptosis, which later we found had been present from childhood; myoclonic movements of the abdominal wall and both upper limbs and weakness of the abdominal wall in the right upper quadrant, where the abdominal reflex was brisker than in the other segments. After a hot bath the hiccups disappeared, and in a few days the myoclonic movements had greatly diminished in frequency and vigour.

If the original illness be regarded as an attack of encephalitis lethargica this patient had an acute recrudescence of the infection after the unusually long interval of five years. It should be remembered that a recrudescence might occur in cases in which the original attack appeared to be slight.

During the past year Mr. Duncan, late house-physician to the Medical Unit, London Hospital, had carried out an investigation on the after-effects of encephalitis lethargica in patients who had been admitted to the hospital between March, 1913, and September, 1921. During this period of three and a half years there were 136 patients, 35 of whom died in the acute phase of the illness. Of the remaining 101, 83 were traced and examined at least one and a half years after their discharge from hospital. The majority of the survivors showed defects, either severe or slight. Mental disorders, varying from defective memory or emotional instability to moral degradation and dementia, were found in nearly seven-tenths of the patients. The high proportion of cases in childhood and early adolescence was striking, for in more than one-half the age was under 20 years. There were nine children who had been under 6 years of age at the time of the acute illness, and six of them two or three years later were backward in mental development. Moral perversions, such as purposeless stealing, outbursts of rage with destructiveness, neurcses, and periodic automatisms were met with, especially in children.

8. The prognosis should not be based on symptoms, but early recognition, on the individuality and intensiveness of the treatment, which in turn may be modified according to a study of the reactions of the personality.

#### DISCUSSION.

Dr. C. P. STOKES (London) said that Dr. Henderson had laid down no absolute rules governing the prognosis in adolescent insanity, but indicated the opportunity afforded to every intelligent student of human behaviour for formulating a rational opinion upon the case of the individual patient. In this matter of prognosis there was a wide difference between the psychiatry of Kraepelin and the psychiatry of common sense. Dr. Henderson had pointed out that the patients whom they were discussing often failed to come within the range of proper treatment until the stage for preventive treatment was past. One of the reasons for this was, as he said, the ignorance of the general public in these matters and their tendency to overlook peculiarities of conduct, or to take cover behind the blessed excuse of "nerves." Educational propaganda in this direction was sorely needed, and there were signs that this was forthcoming. The fault, however, was, Dr. Symonds felt, not wholly with the layman. The average medical student in the course of his curriculum had scarcely any opportunity of acquainting himself first-hand with such problems as they were discussing. Formal lectures and demonstrations taught him very little, and as a rule he went into practice with a feeling that cases of mental disorder—major or minor—belonged to the province of the professional psychiatrist, who had some mysterious formula for dealing with them, and that such cases were outside the sphere of his own usefulness. Hence the regrettable tendency among members of the medical profession to encourage the hypothesis of "nerves" until the stage of preventive treatment was past and the patient's personal trends demanded certification.

This defect in the system of medical education would not, Dr. Symonds believed, be repaired until they had established observation wards for mental cases in the teaching hospitals. The advantages of this plan would be threefold: (1) The very fact of the existence of such a ward in a general hospital would make the student realize that the treatment of mental disease was an integral part of medical practice; (2) the student could also have the opportunity of observing in individual cases the part played by the various factors—heredity, habit of mind, physical disease, and environmental stress; (3) the hospital patient would be encouraged to find that he could obtain help in the solution of mental problems outside the walls of a mental institution. If the patient with early symptoms of mental disorders sought medical aid it was to the neurological department of the general hospital that he came. And yet, knew, no facilities for his treatment as an in-patient.

Dr. Henderson had stressed the importance of the environmental factor in cases of adolescent insanity and had indicated the possibility that an individual, who had failed to make a successful adaptation to ordinary difficulties, might preserve his mental health if life was made easier for him while at the same time he was taught to meet his problems more frankly. In practice it was very often very difficult to find a sheltered path for the individual who was handicapped. One of the commonest obstacles was the economic factor, which was especially prominent to-day. It was not easy for a man who had suffered from any kind of mental disorder to find employment. In the after-care of these patients more co-operation was needed between the general practitioner and the psychiatrist. This, Dr. Symonds was sure, would come when psychiatrists in general acquired the habit of talking about their subjects intelligently, as Dr. Henderson had done that day, and when the general practitioner on the other hand learned that of after-care by means of proper organization. There were many charitable bodies and after-care committees who were ready to help, but social service workers were needed in

the study of the reactions of the personality.

Dr. George RIDDOLD (London) was in entire agreement with Dr. Symonds in urging the necessity of making provision in general hospitals for teaching on, as well as investigation and treatment of, mental illnesses in the early stage. Unfortunately it was true that psychiatry was a branch of medicine about which the average practitioner was very ignorant. This was largely the result of two causes: (1) the clinical teaching on insanity at present offered to the student was dissociated from general medical work in the sense that it was almost entirely carried out in asylums. This dissociation must often be a handicap to the teacher as well as a great disadvantage to the student. It might upon as a joke and a source of amusement; (2) the cases used for demonstration were usually examples of advanced mental disorders. He had the most meagre opportunities for coming into contact with illnesses of that kind at their beginning. Altogether he was apt to be handicapped by ignorance—not due to his teacher but to circumstances—that psychiatry had no relationship with medicine as he studied it in the medical wards, but was a thing apart—in fact, a mystery. He knew only how to certify a lunatic, and even in that legal matter was frequently far from being proficient.

The obvious remedy for this general ignorance of an important branch of medicine was to give the student the opportunity and encouragement to investigate mental disorders for himself and in relation with his other clinical work. This could be best done at his general teaching hospital. Such a reform would not in any way call for the elimination of the present teaching in asylums but would greatly increase its value. Dr. Riddold also spoke of the increased understanding of many mental ailments, especially the psychoses of adolescence, that had already followed the study of them as modes of reaction, and its bearing on more accurate prognosis and treatment.

Dr. F. E. STOKES (Portsmouth) discussed the question of the recovery rate in the dementia praecox type of cases, and recalled the fact that Clouston had 15 per cent. of recoveries in five and a half years' work. The figures he gave showed a higher recovery rate among the manic-depressive type than in the dementia praecox type.

The President said that the most important thing was the study of the reaction type of the soil in which the psychosis appeared. If it was a "shut-in" type a deteriorating psychosis was probably present. The greater the exogenous stresses present in any case the greater were the chances of recovery. This dictum was well exemplified during the war. He quoted two very interesting cases, and concluded by pointing out the value of finding the right environment for the patient.

straightforward attack. The interesting points about the case are the rash and the history of acidosis. The child had been taking sodium bicarbonate 7 grains three times a day for some months, and the sudden withdrawal of this in favour of the antifebrile mixture, coupled with the administration of aspirin, may have precipitated the second attack. The child is now, some weeks later, in perfect health.

London, W.

HILARY LEDGERWOOD.

## Reports of Societies.

### THE OXFORD OPHTHALMOLOGICAL CONGRESS.

THE fourteenth annual meeting of the Oxford Ophthalmological Congress was held at Oxford on July 4th, 5th, 6th, and 7th. Members met at dinner on the evening of Wednesday, July 4th, in the Hall of Keble College. The proceedings took place in the Department of Human Anatomy of the University, which had been once more placed at the disposal of the Congress by Professor Arthur Thomson, the University professor of human anatomy. The majority of the members attending the Congress were again housed in Keble College, by the courtesy of its authorities—an advantage which is deeply appreciated and adds not a little to the success of the meeting each year. The attendance, especially from Britain Overseas and from the Continent, was greater than that of last year or any previous year, making the Congress of an even more international character than usual and a record in numbers.

At 10 o'clock on the morning of July 5th a short opening address was given by the Master, Mr. Sydney Stephenson, who received a hearty welcome.

A discussion on the relationship of dental sepsis to diseases of the eye was opened by Mr. W. R. Ackland of Bristol from the dental point of view, and by Mr. W. Lang from the ophthalmic aspect; it was well sustained by Dr. T. Harrison Butler (Leamington), Professor J. Van der Hoeve (Leyden), Dr. S. Lewis Ziegler (Philadelphia), Mr. P. H. Adams (Oxford), Dr. Sandford Gifford (Omaha), Mr. N. C. Ridley (Leicester), Miss M. Gilchrist (Glasgow), Mr. A. W. Ormond (London), and Dr. Richard Kerry (Montreal).

At the close of the discussion the annual general meeting was held, when the Secretary reported that twenty-two members had been elected, making a total membership of 350, and further that the report of the Honorary Treasurer, Sir Anderson Critchett, K.C.V.O., showed that the financial position was sufficiently good to enable the Congress to make a second donation of ten guineas to the illustration fund of the Ophthalmological Society of the United Kingdom.

In the afternoon papers were read by Lieut.-Colonel H. Herbert (Hove), Dr. C. F. Bentzen (Copenhagen), and Dr. H. Gjessing (Drammen), bearing upon the subject of glaucoma. Afterwards Mr. N. C. Ridley (Leicester) read a report of a case of orbital neoplasm. Colonel Herbert's paper was discussed by Professor Arthur Thomson.

On the morning of July 6th the chief contribution was the Doyne Memorial Lecture, delivered by Mr. H. Moss Traquair (Edinburgh), who chose as his subject the differential character of scotomata and their interpretation. The lecturer's work on the subject has achieved world-wide repute, and his admirably delivered address was warmly received. At its conclusion Mr. Traquair was presented with the Doyne Memorial Medal for 1923.

Two papers were taken before the lecture—the first by Dr. Sandford Gifford of Omaha, U.S.A., on intracisternal injections in the treatment of luetic optic atrophy, and the second by Dr. Lundsgaard (Copenhagen) on the Finsen treatment of conjunctival diseases. The latter was of especial interest in that the author, working in the birth-place of the Finsen light treatment, is an authority on the subject. After the lecture Professor Van der Hoeve (Leyden) read a paper on the rare condition known as tuberosc sclerosis and its relationship to Recklinghausen's disease. A rather long morning session was concluded with a paper by Dr. T. Harrison Butler on the organization of ophthalmic clinics and hospitals.

In the afternoon Mr. Rayner Batten showed some beautiful drawings of conditions at the macula, pointing out the value of drawings of the fundus in clinical ophthalmology, and made some remarks upon the training of those who desire to undertake such work. Mr. J. Batten followed, and as an artist gave an extremely interesting contribution on memory drawing by his method of training. Professor Van der Hoeve (Leyden) described some original work on accommodation, and a report by Dr. T. Harrison Butler of his experience with muscle recession and muscle tucking concluded a strenuous day's work.

On Saturday, July 7th, the morning was devoted almost wholly to a discussion, introduced by Mr. R. J. Coulter Newport, Mon., on the diagnosis of coal-miners' nystagmus and its relationship to the Workmen's Compensation Act. An excellent exchange of views took place, to which the following contributed: Dr. J. S. Haldane, F.R.S., Dr. G. H. Pooley (Sheffield), Dr. T. Lister Llewellyn—member of the Miners' Nystagmus Committee of the Medical Research Council—Dr. Elworthy (Ebbw Vale), Dr. T. Harrison Butler (Leamington Spa), Professor Van der Hoeve (Leyden), Mr. Percival Hay (Sheffield), Mr. R. Dickson (Newcastle, Staffs), Mr. Cridland (Wolverhampton), Dr. Stewart Barrie (Glasgow), Mr. A. Paterson (Durham), Mr. J. Jameson Evans (Birmingham) and Mr. Herbert Caiger (Sheffield).

A paper by Dr. T. Stewart Barrie on colour vision in amblyopic eyes associated with strabismus convergens followed, and was discussed by Dr. T. Harrison Butler. This concluded the proceedings of the Congress.

The official dinner was held in the Hall of Keble College on Thursday night, and among those present as guests were Mr. W. R. Ackland, Sir Archibald Garrod, K.C.M.G., and Professor Arthur Thomson. On Thursday afternoon a garden party was given at St. John's College, Lincoln, by Colonel C. G. Douglas, C.M.G., Fellow of the College, acting as host. On Friday afternoon, after tea in Keble Gardens, a visit was made to the Pitt Rivers Museum when the curator, Mr. Henry Balfour, kindly pointed out and described many of the objects of interest.

The Congress may well be said to have again this year realized the aim of its founder, the late Robert W. Doyn, by combining good work with the opportunity of members becoming more closely acquainted with one another.

### THE "FAILED FORCEPS" CASE.

At a meeting of the Edinburgh Obstetrical Society held on June 13th, with the President, Dr. LAMOND LACKIE, in the chair, Dr. D. SHANNON read a paper on the "failed forceps" case and its treatment.

Dr. Shannon said that by a failed forceps case was meant a case in which forceps had been applied and efforts made at extraction, without the desired result. Reviewing a series of cases treated by himself and his assistants, he found that out of 2,720 full-term deliveries, 70 cases, 2.6 per cent., came under this category. A more detailed analysis showed the cause of the dystocia to be as follows:

- Contracted pelvis, in varying degree, in 52 per cent.
- Occipito-posterior positions of the vertex in 26 per cent.
- Post-mature cases.
- Brow presentations.
- Face presentations.
- Retraction ring.
- In some of the cases no cause could be found.

The mortality, morbidity, and the great amount of invalidism following the treatment of these cases was, in Dr. Shannon's opinion, a reflection upon the art of obstetrics: 7 per cent. of the mothers died, and 50 per cent. developed temperatures in the puerperium; 60 per cent. of the children were stillborn. Two of his cases developed vesico-vaginal fistulae; two cases had ruptured the symphysis pubis; and in two rupture of the uterus took place. One became insane as a result of septic infection and in nearly every case tears of the soft parts were present in varying degree.

The cause of this great mortality and morbidity, Dr. Shannon asserted, lay not with the cause of the dystocia so much as with the want of judgement shown by the practitioner who operated in the first instance. He deprecated the too early application of forceps, and also urged the practitioner not to apply instruments until a proper diagnosis had been made as to the size of the foetal head relative to the pelvic brim in cases of contracted pelvis. Nature should be given a chance to play her part, more especially in those cases in which the occiput lay posterior. He commented on the great necessity of preliminary examination three weeks before the onset of labour in all cases, and remarked that in very few of the cases under review had any examination been made at that time.

Some of these cases were admitted to hospital in a dying condition and died before any obstetrical treatment could be carried out. Others were infected and torn to a marked degree. In a few instances the vagina was practically torn to ribbons. Cases in such a complicated condition gave the constant little chance of success.

In cases of contracted pelvis in which the child was dead, Dr. Shannon said that he always performed craniotomy. The same treatment was recommended in cases in which the child was obviously dying. In some cases he performed craniotomy on the living child rather than the classical Caesarean section, as under the circumstances the latter operation was too risky for the mother. Lately he had performed Caesarean section with a lower uterine segment incision in these cases, to test whether it was safer for the mother than the classical operation, but so far he had not reached a decision. Many cases in this group were, with excellent results, left to Nature after the relative size of foetal head to pelvic brim had been ascertained. In other cases a second operation succeeded because the forces of admission of the patient to hospital, had caused a marked diminution of the diameters of the foetal head by moulding. Dr. Shannon did not recommend the operation of pubiotomy in these cases. In some instances in which the occiput lay posterior he gave Nature a chance, and was rewarded often by spontaneous deliveries or easy forceps operations. In other cases he turned the occiput anterior and delivered by forceps. In the occipito-posterior persistent case he advocated rotation of the occiput, and failing that delivery by forceps. The treatment of the other groups were also reviewed in a detailed manner. In conclusion, Dr. Shannon said that he wished to bring before the notice of the general practitioner the importance of expert advice and aid being called in early in these serious cases, and the danger of delay in sending them into hospital.

The paper was discussed by Drs. H. H. FERGUSON, KAPPE PATRICKSON, OLIVIER MCHENRY, R. W. JONESTON, JAMES JOHNS, ROSE, F. J. BROWNE, H. S. DAVIDSON, SOMERVILLE, and the President.

CLINICAL DISCUSSION AT CORK.

A meeting of the University College, Cork, Scientific and Medical Society (Medical Section) was held on June 11th, with Professor C. Y. PEARSON in the chair, when Professor W. ASHLEY CURRAN presented a case of Little's disease in a child aged 6, and pointed out the differential diagnosis of this form of cerebral palsy from other congenital paralyses of infancy and early childhood. Drs. J. M. O'DONOVAN, MONTAGNA, R. C. CURRAN, and J. M. O'DONOVAN contributed to the discussion of the case, in which was pointed out the depressing contrast between the academic accuracy of diagnosis of such cases and the inadequate treatment in our present state of knowledge.

Professor C. Y. PEARSON presented a specimen of a malignant stricture of the pelvic colon.

The patient, a man aged 55, had suffered thirty years previously from dysentery, and had been treated during the past two years for abdominal pain and constipation. On coming under the care of a specialist, he was found to be suffering from symptoms of sub-acute obstruction, and declined operation. The lower bowel was emptied by a small saline enema, slowly administered, and a hard mass was then palpable halfway between the umbilicus and the anterior superior spine. Subsequently the patient accepted operation.

THE DUCTLESS GLANDS.

A MEETING of the London Association of the Medical Women's Federation was held on June 12th, with Dr. LOUISA MONTAGNA, President, in the chair, when Professor WILFRED CURTIS spoke on the physiology of the ductless glands. She emphasized the importance of co-operation between physiology and medicine in endocrine study, so that unnecessary repetition of experimental work might be avoided, and the great quantity of information that had accumulated might be accurately assessed. Dr. CURTIS read a short paper on the ductless glands from a therapeutic point of view, pointing out the need for standardization of preparations. Dr. ROSA FORD and that in her experience in general practice she was making less use of ductless gland preparations than in former years. She was impressed with the importance of securing normal intestinal function in avoiding and treating dysfunction of the ductless glands. Dr. ALFRED, Dr. KING, and Dr. SAYRE also took part in the discussion.

SINCE 1919 persons visiting French watering places pay a small tax, which in 1922 yielded a total of over eight million francs. *La Presse Thermale et Climatologique* has published a list shows that the greater part of the total amount is recovered at Riviera resorts and other seaside places. There is, in addition, a still smaller tax for the benefit of the Office National du Tourisme; it yielded in 1922 a million and a half francs.

A short discussion followed, in which Dr. J. M. O'DONOVAN suggested that the oedema in such cases, and in the heart-lung preparations in which Professor Barry had mentioned its frequent occurrence, might be due to a vaso-dilator toxin, as in the wound-shock experiments of Cannon and Baylis, in which case the injection of gum-saline solutions might be expected to give relief. Dr. M. CAGNEY emphasized the need for team work in such cases.

## Memoranda :

## MEDICAL, SURGICAL, OBSTETRICAL.

## TREATMENT OF IRITIS WITH TUBERCULIN.

THE following case is of interest on account of the fact that tuberculous infection of the cornea and iris had evidently existed for a considerable time without doing any permanent damage, that local ophthalmic treatment had no effect on the disease, and that tuberculin, unaided by any other treatment, produced a cure in a short time.

A girl aged 15 years was brought to my out-patient department with a history that the right eye had been inflamed for four years; the inflammation had improved at times but had never got quite well. During practically the whole of the four years she had had special ophthalmic treatment, but the condition was as bad as when the attack first started. The left eye had never been involved. The cornea of the right eye showed a diffuse haze, and scattered through its deeper layers were some small yellowish-grey patches of infiltration. The iris was difficult to see owing to the corneal haze, but was contracted, discoloured, and did not react to light. There was intense ciliary and conjunctival injection accompanied by much photophobia and lachrymation, but very little pain. There was no ulceration of the cornea and no corneal staining with fluorescein. The tension of the eye was slightly reduced. There was a considerable degree of convergent strabismus. The patient's general condition was poor, and there were several enlarged glands on both sides of the neck. The condition was considered to be one of tuberculous kerato-iritis. An examination by a physician showed no other obvious tuberculous focus. The Wassermann reaction was negative.

The local treatment prescribed was atropine, hot bathing, and protection of the eye. A tonic was given also. This treatment, the child's mother told me, had been ordered many times before, but had done no good.

At the end of a month, as no progress was being made, injections of tuberculin were commenced, and all treatment to the eye discontinued. At the end of six weeks there was a very decided improvement. The cornea began to clear, the infiltrations in it grew smaller, and the iris, which became more clearly visible, showed some small buff-coloured nodules towards the periphery. The tuberculin injections were continued, the eye receiving no local treatment, and in another month (ten weeks from the commencement of the tuberculin treatment) the cornea and iris were perfectly clear and the ciliary and conjunctival injection had quite disappeared.

I have seen the patient at intervals for the last nine months. There has been no recurrence; the glands in the neck are considerably smaller, and the patient's general health is much improved.

I have to thank Dr. Campbell Faill, tuberculosis officer of this city, for kindly supervising the tuberculin treatment.

E. R. CHAMBERS, F.R.C.S.E., D.O.M.S.,  
Ophthalmic Surgeon, Bristol Royal Infirmary.

## A RECORD PLASMACYTOSIS.

A boy, aged 7 years, had a suppurating gland in the neck which was opened. After doing well for a fortnight he suddenly became ill, the wound became inflamed, and his temperature reached 104° F. Antistreptococcal serum was given. Next day (May 12th, 1919) he had a bright red rash like scarlet fever and the case was notified as such.

On May 13th at noon he was very ill—pulse 140, temperature 105° F. Blood films showed numerous well stained platelets, marked leucocytosis, and conspicuous rodophilia not entirely confined to polymorphs. The differential count was: myelocytes 6, polymorphs 86, lymphocytes 3, mononuclears 5. Neutrophil granules were intensely stained. The majority of the polymorphs had bar, bent, or S nuclei, and two distinct lobes or more were uncommon. In the former Döhle bodies were usual, in the latter vacuolation was frequent.

On May 14th the general condition and films were little altered. The rash was dusky, the tongue raw, the throat much inflamed, and the cervical glands swollen. Next day the general condition was better—temperature 100° F., leucocytosis less, and the differential count was: Myelocytes 1, polymorphs 80, eosinophils 1.5, lymphocytes 10, mononuclears 5, plasma cells 2.

On May 17th the boy was much better; the films showed anaemia, slight leucocytosis, and a differential count of 400 gave polymorphs 50, eosinophils 2, mast cells 0.5, lymphocytes 18, mononuclears 10, and plasma cells 19.

Plasmatocytosis is common in the course of many diseases,

but I have not seen more than 5 per cent. in any other patient. Gruner cites a case of scarlet fever with 11 per cent. (*Biology of the Blood Cells*, p. 270).

Ealing, W.

ROBERT CRAIK, M.D.

## Reports of Societies.

## SURGICAL TREATMENT OF PHTHISIS.

On November 27th the Medical and Surgical Sections of the Royal Society of Medicine held two joint meetings to discuss the surgical treatment of pulmonary tuberculosis. Dr. ROBERT HUTCHISON was in the chair at the first meeting, Mr. C. A. R. NITCH at the second.

Professor P. BULL of Christiania spoke on the subject of extrapleural thoracoplasty with apicolysis. This belonged to the same category in the treatment of pulmonary tuberculosis as the creation of an artificial pneumothorax. Both aimed at producing a collapse of the lung with retraction due to the development of connective tissue; thereby the lesion was healed. This retraction and development of fibrous tissue was the general method throughout the body whereby tuberculous lesions were healed. The lung, however, was at a great disadvantage compared with other tuberculous organs, since without operation it could not shrink further than was permitted by the negative pressure in the pleural cavity, nor further than the stiff thoracic wall could follow. Since artificial pneumothorax was less risky than thoracoplasty the speaker usually tried inflation first. If this were unsuccessful, thoracoplasty might be advised. On the whole the indications for thoracoplasty coincided with the indications for artificial pneumothorax, and the former should be employed when the latter could not be used. In cases of doubt repeated haemoptyses should hasten the decision to undertake thoracoplasty. Theoretically the lung of the opposite side should be healthy. He was satisfied that operation was justifiable when symptoms in the opposite lung had quite disappeared, or when during a long period of expert observation had found them to remain stationary and of slight extent. Even though little or nothing were found clinically, the x rays often caused a proposed operation to be abandoned. Progressive or greatly extended tuberculosis in the opposite lung was a contraindication. He believed that there were a great number of patients with unilateral pulmonary tuberculosis or whose tuberculosis in the opposite lung was only slight or had temporarily subsided. A slight tuberculosis of the larynx or an infection of one kidney was not a contraindication. Absolute contraindications were an advanced degree of infection in the other lung or a bad general condition. A cavernous unilateral pulmonary tuberculosis gave a much more unfavourable prognosis after thoracoplasty than the infiltrating shrunken type. The closest co-operation between physician and surgeon was necessary.

Professor Bull said that he operated with the patient lying on the healthy side, and used the hook-shaped Sauerbruch incision on the back. Resection of ribs was made from the tenth or eleventh up to and including the first. It was vitally important to resect as far back as possible right up to the costal tubercle and the point of the transverse process. He believed a two-stage operation was best. When done in two stages his mortality rate was about 4.5 per cent., in one stage it was 30 per cent. At the first operation the eleventh to fifth ribs were resected; in the second operation the fourth to the first. When he reached the fourth or third rib he performed an apicolysis—that is, he made an incision through periosteum and endothoracic fascia and loosened the top of the lung from the thoracic wall with his finger. This made resection of the two upper ribs more easy. He recommended general anaesthesia. Should there be difficulty in getting cavities in the apex to collapse, intrathoracic transplantation of fat might be found useful. After the operation it was important to relieve expectoration. An extra nurse remained with the patient day and night to support the operated side during attacks of coughing, and to encourage him to expectorate. A good compressing bandage, and morphine or omnopon, were necessary. The temperature often remained high and the

pulse frequent for four or five days; then in favourable cases it fell to about normal with considerable diminution of pain. The amount of sputum often diminished whilst the patient was still in the hospital. A rapid diminution of sputum was a good but not completely reliable prognostic sign as regards lasting recovery. In a considerable number of cases the tubercle bacillus disappeared from the sputum during their stay in the surgical clinic, nor did it return. This suggested a good prognosis. Later there developed a scoliosis of the spinal column with the convexity toward the diseased side, the reverse of the post-empyemic scoliosis. The post-operative rise of temperature was probably due to increased absorption of toxins from the collapsed lung which, like a sponge, was pressed partly free from its contents.

Professor Bull then gave several instructive tables illustrating his results. Out of 56 left-sided extrapleural thoracoplastic operations he had had 2 deaths from operation (3.5 per cent.); of 36 right-sided cases 7 deaths (19.4 per cent.). The right-sided operation was therefore considerably the more dangerous. The following table may sum up the speaker's results:

*Results of Fifty-five Extrapleural Thoracoplastic Cases observed from three to nine years after Operation.*

Dead, 23 = 51 per cent.—	
From operation ... ..	5 = 9 per cent.
From tuberculosis ... ..	22 = 40 "
From other causes ... ..	1 = 1.8 "
Still alive, 27 = 49 per cent.—	
Symptomless and able to work ...	17 = 51 per cent.
Tuberculous ... ..	10 = 13.2 "

The danger to the patients lay in a new outbreak in the other lung, often several years after operation.

Dr. CLIVE RIVIERE said that cases suitable for pneumothorax usually came to the physician with disease already crying out for treatment. It was only a particular type of pulmonary tuberculosis which was suitable for collapse therapy, and this type often reached a definite diagnosis only when moist sounds already covered a good part of one lung. Earlier the disease escaped diagnosis because it was deep and out of reach of the stethoscope. The common type of deep-seated or hilus tuberculosis was double. In the fortunate cases suitable for collapse therapy only one lung was seriously affected. The x rays showed an "interstitial" spread on both sides, but the parenchymatous outbreak following this was in these cases confined to one side only. The majority of such cases were found in adolescence. It was common to see patients with advanced one-sided disease clinically but double disease to x rays. Therefore a radiogram should always be used in deciding suitability for pneumothorax. The better lung was seldom quite free; there was generally a thickening of strands seen by the x rays, but if these were not very lumpy and if the outline of the lung field was clear or contained only a few sharp-cut shadows the lung would probably function safely whilst the other was collapsed. To the stethoscope the better lung would probably appear quite clear, and if at a later stage the disease spread and became active in this lung the first clinical signs were found, not at or near the apex, but about the mammary region or in the axilla. It was remarkable how in the class of case described the disease might have spread through the whole lung, and surface signs might have been present for a long time, and yet complete collapse by pneumothorax might be obtainable. A lung should never be presumed adherent without pneumothorax having been tried. Negative pressure might draw heart and mediastinum into one side of the chest and deform the diaphragm without any pleural adhesions being present. When pneumothorax completely failed through an adherent pleura, or only a partial and ineffective pneumothorax could be obtained, the question of further surgical measures would arise. In cases of a partial pneumothorax often a patient trial would be needed before its work could be fully gauged. If its effects on symptoms were unsatisfactory, if large cavities were left uncollapsed, or if, in spite of measures to prevent it, large febrile reactions followed the refills, additional methods of lung collapse should be used. The cauterization of adhesions might help, but usually thoracoplasty, with or without a pneumothorax, would be necessary. He himself had had no experience of a combined pneumothorax and thoracoplasty, but in certain

cases it should prove rational by avoiding the permanency which was perhaps the most embarrassing feature of thoracoplasty and similar operations. If pneumothorax alone had been tried and had failed, the "better lung" must be examined with yet more meticulous care before a thoracoplasty was advised, for further factors now came into consideration—the finality of this further move, the strain of operation, and the yet more violent mechanical and toxic disturbance brought about. In these cases there must often be a choice between an operation of doubtful outcome and, on the other side, certain death. The patient's interest must be placed before the physician's reputation, but these operations should not be dragged into undeserved discredit. Of other indications and contraindications, good nutrition was an important asset and cachexia a decided contraindication. The heart would have to meet considerable strain and must be fairly sound. Intestinal tuberculosis was an absolute contraindication, but a moderate laryngeal lesion might be allowed. Certain methods of operation other than thoracoplasty might be cited. Multiple adhesions might be separated by opening the pleura through an intercostal space; single or few adhesions might be divided without opening the pleural cavity. These methods were sometimes useful. With regard to pneumolysis, the parietal pleura was easily stripped from the endothoracic fascia; thereby the lung was collapsed, but a space between lung and chest wall remained. This could be filled with gas or air or with fat or paraffin. In each case the risk of sepsis was considerable. The disadvantages of thoracoplasty as compared with pneumothorax were: first, the strain of the operation and the rapid collapse of the lung with auto-intoxication and risk of aspiration pneumonia; secondly, the collapse was permanent—there was no return; and lastly, the collapse might not be sufficiently complete to arrest the disease. In this case supplementary measures might be used.

Mr. H. MORRISON DAVIES agreed that pneumothorax should be the first surgical manoeuvre tried. If the collapse were complete the result was excellent. Often, however, pneumothorax failed completely or partially because of adhesions. If there were a broad adhesion and pneumothorax was continued the adhesion did not break but the lung ruptured and a pyo-pneumothorax resulted. Other methods of removing adhesions were to introduce a thoracoscope and remove them by the electric cautery; others might be dealt with by a special tenotome; and yet again, in cases more extensive, the chest might be opened and the adhesions exposed, ligatured, and cut. Another method he would like to mention was section of the phrenic nerve. This was useful in cases of pneumothorax where there were adhesions between base of lung and diaphragm. In these patients cough was a troublesome symptom. If the phrenic nerve were divided the cough went. If the disease were localized to the upper lobe the speaker advocated apicectomy. Paraffin or wax, not gas, should be used to fill the cavity remaining. The danger lay in the fact that paraffin might be extruded later, with the risk of secondary infection. Fat was better, but this might liquefy and then be extruded. If the adhesions were more extensive thoracoplasty was necessary. The speaker had found that local anaesthesia alone was too great a strain. He now used novocain, alcohol to paralyse the intercostal nerves, and a little chloroform. He strongly advocated the paravertebral incision. The ribs must be removed right back to the transverse processes. The first rib especially must not be neglected. He had found a one-stage operation best. There was little deformity. In children the axillary incision might be used.

Dr. E. BEAUMONT emphasized the very small number of patients suffering from pulmonary tuberculosis who required any operative treatment. The percentage had been variously estimated at from 2 to 20. He would suggest that the indications for a pneumothorax were: (1) patients with unilateral lesions who failed to respond to one month in bed on absolute rest; (2) similar patients who responded to rest in bed but in whom getting up was followed by active manifestations; (3) haemoptysis which did not respond to other measures. The type of operation necessary was a decision for the surgeon and not for the physician.

TUBERCULIN AND THE TUBERCULIN DISPENSARY.

IN 1909 the Tuberculin Dispensary League was founded with the object of demonstrating the possibility of treating the tuberculous poor by Dr. Canac Wilkison's method of tuberculin administration. For three years at Kensington, and thereafter at Chelsea, several hundreds of patients passed through the dispensary, and in the opinion of the promoters of the scheme appear to have benefited greatly. Owing partly to a desire for financial assistance, and also for more public recognition, the executive committee of the league drew up a petition to the Minister of Health requesting that the work should be examined and reported upon. This petition was handed to the secretary of the Medical Research Council, who asked for the submission of a report by the committee as to the value of the tuberculin treatment. Following the reception of this report the Medical Research Council arranged for an examination of the work, and accordingly deputed three medical men to investigate the work of the dispensary, and to express their opinion of the results obtained. So far as can be judged from what Dr. Canac Wilkison says, these three medical men were not given the benefit of his personal opinion; they were received by the honorary treasurer and by one of the assistant medical officers. The sequel of this inquiry was the preparation of a confidential report which stated that Dr. Canac Wilkison's system of treatment "did not appear to have claims over other methods of treating tuberculous either with or without tuberculin which would justify its general adoption." To this Dr. Canac Wilkison has replied by the publication of an essay on the tuberculin dispensary for the poor.

As may easily be imagined, it is quite impossible to form an unbiased opinion of the reply when one has not had the opportunity of reading the original document to which the reply has been made; and however emphatically he may write, and however pertinent—or otherwise—may be his strictures on other methods of treatment, it is only fair to say that he can scarcely hope to carry conviction to those who are interested merely in ascertaining the facts on which his case is based, for these facts are not provided. It is true a few summary data are given, but owing to their incompleteness they mean very little. We have compared them—as far as it is possible to compare them—with the Bradford statistics,\* and find that there is no marked superiority to which they may lay claim. But on this we would not place much emphasis. The real point is that there are no figures, so far as we know, which are quite comparable with those from Chelsea, and it is hence impossible to form any adequate opinion on their meaning.

If Dr. Canac Wilkison is really convinced of the superiority of his method—and of this there is no reasonable doubt—we would advise him to collect the notes of all the patients who have passed through his hands since 1910, to summarize them in the way in which the Midhurst notes were summarized, to obtain their after-histories as fully as possible, and to submit them to the scrutiny of a first-class actuary who may be trusted to draw up an impartial report upon them. Supposing that this report is favourable we shall be justified in concluding that the results

obtained by Dr. Canac Wilkison surpass those obtained by other physicians. But—and it is important to emphasize this point—we shall not be justified in concluding that these results are due solely to tuberculin. This may well have been one of the factors, but it is obviously not the sole one, for the patients apparently receive much the same general education as to their mode of life as is given in the ordinary tuberculosis dispensaries. In order to prove undubitably that treatment by Dr. Canac Wilkison's method of tuberculin administration is superior to all other forms of treatment it will be necessary for him to take two series of patients, comparable alike in age, sex, stage of disease, occupation, and place of residence, and to treat them identically, except for the sole difference that one series receives tuberculin injections and the other does not. Only in this way will he be able to prove his case. Until this is done judgement must be reserved.

FINSSEN LIGHT FOR LARYNGEAL TUBERCULOSIS AND LUPUS VULGARIS.

DR. OVE STRANDBERG, of the Finsse Institute at Copenhagen, delivered an "occasional lecture" at the Royal Society of Medicine on December 3rd on the treatment of rhino-laryngeal tuberculosis by Finsse light baths. He in London (Count Lauritz), who referred to Queen Alexandra's interest in the Finsse method. Dr. Strandberg said that the treatment of rhino-laryngeal tuberculosis by means of Finsse light was not entirely new. About nine years ago he published his first few cases, and since that time the number of cases had been greatly increased and the results thoroughly tested. The Finsse bath consisted of an electrical carbon arc light used in one of two sizes. The smaller was an arrangement of three lamps using 20 amperes and 55 volts each, for the treatment of the more serious cases which could not sit up, and the larger embodied two lamps, each of 75 amperes and 55 volts, which made it possible for six or eight patients to be treated at the same time. Patients with tuberculosis of the larynx were placed in the Finsse bath for from ten to fifteen minutes on each of the first few days, and the application slowly increased up to the full dose of two and a half hours every alternate day. Patients with lupus vulgaris, if their general health was good, could begin with thirty to forty-five minutes' application with the large lamps. After the Finsse bath a rapid shower-bath was always given, and the out-patients could then go back to their work. The first baths were followed by an erythema of varying strength, darkening in a short time to a brown pigmentation, and once this was obtained the patients suffered no further inconvenience. Contradictions were shown only in certain heart and kidney troubles. When treating lupus vulgaris he always combined with the Finsse bath surgical treatment or electro-coagulation simultaneously, and he did the same also in many cases of tuberculosis of the larynx. He showed the results of this treatment in 579 patients treated for lupus vulgaris over the years 1913 to 1921. Of this number 504 were pronounced cured; 155 of the cured cases had been under observation subsequent to cure for more than twelve months. There had been recurrences in 25 of the 504 cases, and 21 of these had been cured again, 9 of them having kept well for more than twelve months. In tuberculosis of the larynx—in which category he did not include ordinary laryngitis, but only the inflammatory or ulcerative affection of the larynx—the cases the patients were cured again, 9 of them having kept well for more than twelve months. In tuberculosis of the lungs—the gave particulars relating to 100 patients. In 53 of these cases the affection had been of the larynx which occurred among patients with tuberculosis of the lungs—the gave particulars relating to 100 patients. In 53 of these cases the affection had been of the larynx which occurred among patients with tuberculosis of the lungs—the gave particulars relating to 100 patients.

Dr. S. VERE PEARSON said that before deciding upon a thoracoplasty the general condition and symptoms of the patient must be considered rather than any physical sign. Prognosis should be considered from two points of view: what was likely to happen if the operation was undertaken, and what if it were not attempted. The anaesthetic should be both general and local. He wished to put in a plea for thoracoscopy and removal of adhesions with the electro-cautery and a pneumothorax. This procedure was simple and scientific. The danger of cutting the lung with a knife was avoided. The risk of surgical emphysema was lessened by pulling down the skin before making the incision and so making a valve-like opening. A tight bandage was very important.

Mr. J. E. H. ROBERTS quoted some important figures from the work of Continental surgeons. Saugman and Gravesen had 45 cases in which incomplete pneumothorax only was possible by reason of adhesions. Of these, 11.1 per cent. were finally able to work; 86.7 per cent. died from tuberculosis. In 77 cases no pneumothorax was possible. Of these, 11.8 per cent. recovered sufficiently to work, 31.8 per cent. died. Sixty-nine cases were treated by thoracoplasty: after two to seven years 44.9 per cent. were able to work; 10.1 per cent. were alive but unable to work, and 42.1 per cent. were dead from tuberculosis. Jacobaeus and Einar Key had 44 cases treated by thoracoplasty. The following results were disclosed three to seven years later:

Able to work	...	...	...	...	27	per cent.
Better	...	...	...	...	18	"
No better or worse	...	...	...	...	7	"
Dead from operation	...	...	...	...	11	"
Dead from tuberculosis	...	...	...	...	26	"

All the figures included early operations. Some were done in one stage and some in two stages. There was therefore a case firmly made out for thoracoplasty. Posterior resections of the ribs should be continued to the transverse processes. Professor Bull, by combining thoracoplasty with apicolysis, had got rid of the objection that thoracoplasty did not compress the apex. Mr. Roberts administered glucose and saline twenty-four hours before operation and bound broad strips of strapping on the chest after. If there were present a fairly high degree of pneumothorax care should be taken in doing thoracoplasty lest cardiac symptoms occurred.

Dr. L. S. T. BURRELL recommended the operation of cutting the phrenic nerve. It was simple, gave additional rest to the lung, and did not permanently paralyse the diaphragm. He emphasized the serious nature of thoracoplasty. By doing this they burnt their boats. Other methods of resting the lung could be stopped if the other lung made this necessary; but thoracoplasty was final. Mr. TUNOR EDWARDS advocated in many cases thoracoscopy and cauterization of adhesions. He showed a very instructive series of pictures illustrating the views obtained through the thoracoscope, the types of adhesion seen, and the best methods of dealing with them. Dr. CURRIER emphasized the value of radiology in deciding the operation of choice.

### THE NERVOUS CHILD.

A discussion on the nervous child took place at a meeting of the Medical Officers of Schools Association on November 28th. Mr. R. C. ELSLIE presided.

Dr. H. CRICHTON MILLER, in opening the discussion, said that he proposed to restrict his remarks to some fundamental psychological conceptions of the child and its difficulties. Those who had to deal with education in any shape or form must never forget that they were supervising the child in his long, tedious, and difficult pilgrimage from the outskirts of society towards its centre. In that pilgrimage the child was called upon to make numerous new adjustments. Hardly was one adjustment stabilized before the time came for another. In the process of making those new adjustments the child often fell behind. A large number of children who came into the world were problem children from the very beginning, and no sort of education or environment would ensure a smooth progress for them. Such children were bound to meet special difficulties owing to their hereditary make-up. In the present discussion, however, these children must be left alone, and he would

deal only with the child who began with a normal equipment and had a normal environment and who ought to make good as an adult. Unfortunately, the child who started well in this way often went to pieces, and psycho-analysts were constantly coming across adults who were nervous wrecks, and whose wreckage was traceable to some period in their early development when they began to go "off the lines." It must be agreed frankly that the teacher and the school would be beaten every time by the parent and the home. Those of them who had to do with education must accept the fact that they had not the last word to say as to failure or success. Whether the child went to a great public school at the age of 13, to a preparatory boarding school at 9, or even to an elementary school at 5, he went in each case as an individual already developed to some extent—he went as one who had up to a point made an adjustment to a social environment suitable to his years. Often, however, something was lacking about such adjustment. The child of 7 or 8 should be beginning to throw off the shackles of maternal magnetism, yet often at this age there remained a quite morbid and exaggerated craving for maternal protection and comfort. The wife of the head master of a good preparatory school said to him that the little fellows who came to such a school now at the absurd age of 8 really had little use for the masters; she and the matron were the only people in the school who meant anything to them. If the child were cut off from sources of maternal protection he might be expected to break down in one form or another. At the usual age for entering a public school one might expect a certain amount of independence and readiness to accept responsibility, yet here again it was often found that the child's moral and emotional development had been retarded, and the reason was that the father had been a source of fear, if not of terror, in the home, while the mother, instead of being ready to let go the emotional domination which was her prerogative during the first seven or nine years of the boy's life, was quite definitely holding on to that domination. Some boys of 14 in the public school were still "mother's darlings," and it was no use expecting from such boys a normal reaction to social environment. The child was naturally anxious to obtain status in the eyes of his fellows. Some children tried to do it by "showing off," or by various forms of self-assertion, while some became criminals. There was no limit to the number of ways in which the immature specimen of the human species would seek to obtain status in his social environment. It was necessary to go behind this desire to acquire status. The child was suffering from a sense of inferiority. The world into which it had been born was largely an adult world in which the child was incomplete and immature and was reminded on every side of its incompleteness and immaturity. The children and adolescents who made good adjustments were those who accepted the necessary degree of inferiority. But a certain if not a large percentage of children refused to accept that sense of inferiority, and therefore they "compensated" by seeking superiority in some morbid fashion. Many nervous children were children suffering from a very profound sense of inferiority for which they were compensating all the time by an enormously exaggerated or overdetermined manifestation of superiority. The conflict between the attempt to assume superiority and the consciousness of fundamental inferiority produced the nervous make-up.

Dr. Crichton Miller went on to show how this great factor of inferiority might be studied in a special way with reference to the sexual life of the child. There were three different aspects of this which he asked the audience to consider. The first was nocturnal enuresis, one of the most interesting problems in the whole of medicine. In this condition there was no doubt a physical element—by which he did not mean an anatomical element—depending upon some lack of endocrine equilibrium, having something to do with the pituitary certainly, and possibly also with the thyroid. Many of these cases were cured by thyroid treatment alone, but many were not so cured. Nocturnal enuresis, however, was also the result of auto-suggestion. The child became terrified at the thought of its repetition, and the fear was enough to bring about the act. Also it lived within an atmosphere of suggestion.

increase in the number of pharmacy jars required, with an inevitable deterioration in their quality. During the seventeenth and eighteenth centuries they were generally smaller in size and more sober as regards decoration; only large and rich pharmacies could afford jars of the size and magnificence of those produced by the Ligurian workshops, which served rather for decorative purposes than for the preservation of drugs.

## DANGERS TO HEALTH IN PHOTO-ENGRAVING.

In March, 1922, the Italian Federation of Photo-Engravers published a report on health conditions among its members in Rome, calling attention to the fact that several had died within a comparatively short period. It was suggested that the poisonous substances with which photo-engravers work might be a cause of disease, and that unhygienic conditions of work might lower the power of resistance. The federation called for investigation of conditions in photo-engraving shops, and of the effects of the processes used on health. The Industrial Hygiene Service of the International Labour Office took up the question, and obtained information from Great Britain, Germany, Italy, the Netherlands, and Switzerland; the data collected by this investigation do not altogether bear out facts hitherto alleged. An essential feature of one common process of photo-engraving is the placing of a metal plate, usually of zinc, to which the image to be reproduced has previously been transferred by photographic methods, in a bath of nitric acid. The image itself is protected by a resistant, such as powdered bitumen, colophony, or "dragons' blood," and the exposed portions of the plate are etched out by the action of the acid. The details of the process vary considerably in different countries, more particularly with regard to the construction of the etching bath and the strength of the acid employed; some etching baths are covered in and provided with a fume shaft, others are open and of a more primitive type. The conditions of work vary also in different countries. Dr. Legge reports that in Great Britain photo-engraving is generally conducted in the upper rooms of the building, often on the top floor, as a good light is needed; good natural ventilation is also thus secured. In Rome it was found that photo-engraving was carried on on the second, first, or ground floor, and in one case even in the basement, but the etching baths were generally in the open air or in an open shed. The reports from some countries give the impression that equipment and hygienic conditions have not kept pace with trade development, and that too necessity for ample ventilation has not always been recognized. The chief danger to health in photo-engraving arises from the escape of fumes from the acid etching bath. The conditions under which these fumes appear were investigated in the chemical laboratories of the Netherlands Labour Inspection Department, and led to the following conclusions. Solutions of nitric acid, from 10 to 25 per cent. absolute strength, when brought into contact with zinc give off a large quantity of nitric oxide vapours which, on mixing with the air, become nitric dioxide, the notorious brown fumes. When inhaled they penetrate into the pulmonary alveoli and combine with vapour exhaled to form nitric or nitrous acid. If this process is intense serious affections of the pulmonary alveoli may be set up, with the typical character of acute poisoning by nitrous fumes. The danger from these fumes is increased when the etching is carried out in an open bath and when the nitric acid is used in higher strength than 15 per cent. Dr. Legge reports that in this

condition had been aggravated or had remained cured, and all who had died. In the 55 cases cured with surgical treatment in 19. The period of follow-up of these cases had extended over twelve months and many were completely aphonous before treatment. Of 78 of them regained a full and clear voice; 37 with difficulty in swallowing, and 32 were freed entirely of trouble. The number of treatments with the light each case averaged about 86. He claimed that the percentage of cures of tuberculosis of the larynx was a proportion than that obtained so far by any other method. Moreover, the affections of the larynx which he had been taken earlier the recovery rate would have been higher. About three-quarters of the patients were in a very advanced stage, and no doubt that the recovery rate was supported by conditions of good nutrition, and the result was all the more remarkable on that account. Sir St. Clair Thomson, given by Dr. Strandberg showed that this treatment had in the press at the moment his own results first sanatorium and afterwards local treatment, over a period of ten years. His results showed that the laryngological tuberculosis was well worth a trial. Dr. Strandberg's method, which did not exclude other resources, gave, by the statistics brought forward, more than 50 per cent. of successes, and was full of promise.

## OLD ITALIAN PHARMACY JARS.

On Arturo Castiglioni of Trieste has recently published an article emphasizing the importance of ceramic jars of medicine. It is illustrated by pictures of the history of medicine. The collection of the pharmacy jars of the fifteenth century. Italian jars, although in existence in convents and royal monasteries, did not assume the form of public institutions until the middle of the sixteenth century. The apothecaries then formed corporations which were almost always associated with those of the medical profession, and the apothecary's shop then came and remained for several centuries a centre of legal culture. The apothecary, besides being a dealer of drugs, also used to sell books and works of art, in addition was often an astrologist or alchemist. The apothecary's shop was the chief sphere of the physician's activity. Not only it served for the reception of patients and the treatment of their wives, as is seen in many contemporary pictures, but also as a resort for scientific and professional discussion. It was the birthplace of experimental medicine. Moreover, it was in the Italian pharmacies of the fifteenth century that ceramic art reached its highest point and found its most beautiful expression, as in the larger hospitals, such as that of S. Maria della Scala at Florence and that at Siena, where the jars and the shelves on which they rested were decorated by the spirit of the Renaissance, not only Italian medicine become freed from Arabian but ceramic art, as exemplified in the pharmacy

The admonitions of its elders, and the precautions employed, such as the use of a waterproof sheet, all encouraged the very thing which the child and its elders wanted to prevent. Nocturnal enuresis was the most definite symptom of the cradle condition; the child who in adolescence was resisting development held on to this symptom as a thing symbolical of the cradle. And the child who felt that he could not help his symptom realized that the scoldings and threats were unjust, and that he was the victim of an uncomprehending adult society; thereupon he turned to acts of revenge, and an astonishing number of petty thefts were committed by boys who suffered from nocturnal enuresis. The speaker's next point was masturbation. It was very important that the emotional atmosphere should be cleared away from this subject. All of them had suffered from well intentioned masters and chaplains who had dealt with the subject of masturbation on the most solemn and sacred basis. In all sex matters he was an idealist, but he did feel that extreme harm was done by presenting to the child his conflict of masturbation, which was largely a simple biological one, as though it were one on which his future depended, possibly his immortal destiny. This was grossly wrong, and only rarely did such methods have a good result. They might cure the symptom, but their influence on character was not wise. Finally, he dealt with homosexuality. Every boy and girl normally passed through a phase of potential homosexuality, and when active homosexuality was found amongst school children it was necessary to remember that it was merely a smouldering fire which had been fanned into a flame. It was most disastrous, thoroughly bad for the community and the social group; but, nevertheless, it should not be regarded in the same way as adult homosexuality, which was a perversion. In the child homosexuality meant merely that the normal romantic homosexuality which belonged to this phase of development had most unfortunately turned from romance into passion.

Dr. H. C. CAMERON, who dealt with the subject from the physical point of view, repeated some of the observations made in his paper read at the Portsmouth Meeting of the British Medical Association (BRITISH MEDICAL JOURNAL, November 24th, 1923, p. 963), but inasmuch as he had had no opportunity in that paper of dealing with the treatment of the nervous child he thought he might say a few words on that subject. After showing some photographs of the amyotonic child, illustrating the typical pose of the child suffering from nervous exhaustion, he said that the first line of treatment for the muscular condition would be drill, gymnastics, dancing, and massage. Drill placed the body in a position which was the direct opposite to the characteristic stance of the nervously exhausted subject, and it had more than the effect of a physical corrective. Quickness to act and obey, control and co-ordination, resistance to fatigue, courage, and all the muscular virtues were imparted by drill. With regard to gymnastics, it would be an immense advantage if these could be carried on with the greater part of the body uncovered. The old Greeks knew what they were about in this respect, and the word "gymnastics" meant exercises carried out naked. Without the removal of the clothes the shameful weaknesses were not exposed and improvements were not noted. Massage had immediate benefits in improving the muscle tone, but none of that remote significance which was the essence of drill and gymnastics. In the case of these nervously exhausted children, he would intersperse the exercises with frequent short periods of rest, and the rest position which he favoured was what he called the "Little Lord Fauntleroy" position, the ventral position with the upper part of the body resting on the elbows in front of the fire. He had found benefit also from skin friction. Nervous children always did well at the seaside, where their bodies were whipped into a glow by the winds. Hot and cold baths alternately were useful, followed by friction with the roughest possible towel. Just as improvement in the body showed itself in an improved mind, so improvement in the mental environment showed itself in an improved muscular posture. Another important factor was that in all this management of children they must be prevented from observing all the apprehensions which their somewhat pathetic state aroused in the parental mind.

Mr. R. C. ELSLIE said that although the treatment of

posture seemed to be clearly indicated, the difficulties of improving the posture were very considerable. He had known children to receive most capable instruction for long periods, with practically no improvement. His own feeling was that this postural tonus was a thing which in human beings was not entirely instinctive—not quite the natural thing which would be expected if the regulating centre were in the basal ganglia of the brain—but that it was something learned, and that children showed great differences in the way they learned it. This would point to the existence of the regulating centres higher in the brain than the basal ganglia, rather in the cortex, where one would expect to find the centres of those actions which were at first voluntary and afterwards habitual.

Dr. C. E. SHELLEY referred to the element of nutrition and its importance in respect to the nervous condition. What chance had the food customarily given to a young child to build up a stable nervous system? The child was fed largely on white bread, from which the real value of the grain had been extracted. The child was deprived of the material most likely to promote mental and muscular development.

Dr. ELWIN T. NASH said that these cases were sometimes amenable to suggestion, but at other times a more powerful counter-suggestion, probably from the mother, upset this line of treatment entirely. It was extraordinary how perverse some parents would be. He had desired to hear something from the openers of the discussion on phobias. Here again he found some children yield easily to treatment, while others resisted all his efforts.

Dr. LETITIA FAIRFIELD considered that in the case of some nervous children it was a waste of time and a real cruelty to endeavour at the outset to improve the muscles. These children could not respond to an increased call on their nervous energy; they needed mental therapeutics before these physical methods were applied. She was extremely sorry for the child who had been driven too soon and too hardly into the cold world. If these children were not given some sustenance and comfort in their effort to get rid of the inferiority complex which was at the root of the trouble, the mere effort to force the muscles would result in harm. Of course, when they had improved a little, massage and similar methods might be tried. It was extraordinary how the "Peter Pans," if allowed to open their hearts to a sympathetic recipient, would reveal their fears in all sorts of ways. It was useful to have had emphasized the part which the mother played, not, indeed, in originating a neurosis, but in augmenting and sustaining it.

Dr. L. R. LEMPRIERE said that his reply to the question whether the nervous child was fit for public school life would be that that was the best place for him. His own careful studies at Haileybury College did not suggest that the nervous children were increasing in numbers, notwithstanding the war and its aftermath. He gave some interesting details of exercises which he had instituted, and their results. He advocated the continuance of the use of belladonna in the treatment of nocturnal enuresis. Dr. M. L. DONNIE criticized Dr. Cameron's advocacy of the ventral rest position, which she considered harmful in the case of the weak child.

Dr. CRICHTON MILLER, in a brief reply, could not agree that belladonna, to the use of which he objected, was the solution of the treatment of nocturnal enuresis. He had found thyroid of service in some difficult cases. Dr. CAMERON, also replying, said that if enuresis were to be overcome it could only be by securing the whole-hearted support and understanding of the mother. Undoubtedly the apprehension of the thing persisted in the child's sleeping state. He had found it help matters to adopt different devices according to the child's age. In very young children something in the nature of an amulet was useful.

## THE PSYCHO-NEUROLOGICAL CLINIC AT UTRECHT.

At a meeting of the Medico-Psychological Association of Great Britain and Ireland, held at the rooms of the Medical Society of London on November 22nd, the President, Dr. EDWIN GOODALL, referred in sympathetic terms to the death of Dr. W. Ford Robertson, and a resolution of sympathy with his relatives, and marking the sense of loss which the Asso-

thirty minutes being necessary for this purpose, and afterwards, by re-immersing the salt, exposure to 218° F. for growths can also be inhibited by adding 5 per cent. of sodium bisulphite to the salt, but for hygienic reasons this is not recommended. Another method is to dry the fish to a greater extent than at present, as "pink" organisms will not grow on highly dried fish. The capacity for reabsorbing sufficient water to make the salted cod palatable, however, is lost when the drying has been excessive, and an account of experiments by Dr. Moran and Mr. Druce are appended to Dr. Cloake's report to show this effect of over-drying. One gathers from the report that the "pink" growths in themselves are not necessarily injurious to health, but the conditions of warmth and moisture under which they appear are favourable to the growth of putrescent organisms, which are liable to render the discarded salt fish unfit for food. The relation, however, of the growth of "pink" to putrefaction has not yet been sufficiently investigated.

SICKLE-CELL ANAEMIA.

literature, commencing with 1910, the first four records of single cases, but Dr. J. G. Huck of the Biological Division of the Medical Clinic, Johns Hopkins University, has recently investigated twenty cases and has written a valuable and generously illustrated account of the disease, which is not more than a page or two in length.

RED DISCOLORATION OF SALTED FISH.

only with the open rocking bath; since the introduction of closed baths and more modern methods of immersion in the photo-engraving industry in Great Britain have improved materially, and few complaints are now received. It has proved difficult to obtain precise information on mortality and morbidity among photo-engravers, as separate statistics are rarely kept for this class of workers. In Great Britain the secretary of the Amalgamated Society of Lithographic Artists, Designers, and Engravers says that no severe illness directly attributable to acid fumes has come to his knowledge. He adds, however, that "generally speaking, our experience is that all the members of this society are and probably the time-etcher would be more susceptible than workers in other branches." The report from the Netherlands states that complaints of the effects of nitrous fumes have been very rare in recent years. Professor Loriga reports that the investigation conducted in Rome does not provide grounds for inferring that there is any specific liability to disease among photo-engravers. The chief means that can be taken to protect photo-engravers from the dangers of their trade are adequate ventilation and closed-in-bath working, good lighting, and closed-in-bath working with ventilating apparatus in carry-off and acid baths with venting fumes and of the methods of rendering harmless acid fumes; in the Netherlands printed pamphlets on nitrous fumes have been distributed among the engravers.

## RED DISCOLORATION OF SALTED FISH.

ciation had sustained, was carried by members rising in their places.

Professor D. C. WINCKLER gave an address, illustrated by a series of slides, on "Psychiatrical and Neurological Teaching at the Dutch Universities, especially at the University of Utrecht." He said that the organization of the study of neurology and psychiatry at the universities in Holland had been a very difficult matter. The Utrecht Society of Psychiatry was established in 1871, and it organized many petitions urging proper psychiatric instruction. In 1877 it succeeded in having an enactment passed which was entitled "A Law on Higher Education." At this time there were no recognized examinations in psychiatry, and medical men in asylums were recruited from among military medical men who had returned from the Colonies. Donders strongly favoured the efficient teaching of psychiatry, and the lecturer's eyes were specially opened to the need by Professor Leidesdorff, professor of psychiatry in Vienna. In this country it was the exception to have whole-time professors, but in Holland it was a stipulation that professors should not undertake private practice—a wise provision in some ways, but it did not ensure that the professor was necessarily the best man on the subject. In Holland the paying patient constituted a great financial help to the teaching schemes. The 1877 law permitted the establishment of the Amsterdam Municipal University, the Faculty of Medicine of which operated in that city. In 1885 Professor Winckler was nominated a university lecturer on psychiatry and neurology, and money was set aside for research. The Society of Psychiatry held a number of discussions on the need for the teaching of neurology and psychiatry by one professor. The chief opposition to this idea came from practising specialists. He showed how intimate the two subjects were, and that to place the tuition in separate hands must result in much overlapping and duplication. He contended that even a skilled neurologist was not necessarily a psychiatrist; moreover, psychiatry based only on psychology had proved dangerous, as witness Weinroth's contention, in 1862, that "All alienation reposes on sin." In many asylums the clergyman was accepted as the leader, the physician being relegated to a secondary place. Later, the Society took the ampler title of "The Society of Psychiatry and Neurology," and the two departments were successfully fused. At the Utrecht University students could not be trained as specialists before passing their final examination. It was now possible, as a result of various controversies, to retain specialism within certain limits, but he was anxious as to the future.

A project was successfully started for building a clinic of psychiatry and neurology in Utrecht, but as it was to cost £50,000 some hesitation was felt, and the authorities argued that the best place at which to teach psychiatry was the asylum. This, however, was opposed by the Society, and by the Faculty of Medicine at the University, chiefly on the ground that cases of the various transient psychoses—hysteria, neurasthenia, hypochondria, etc.—were seldom seen in asylums. Matters remained stationary from 1885 to 1891, but in 1892 everything seemed in readiness for commencing the new building. However, a small mistake on the part of the architect led to a controversy between the State and the municipality, and there was a further delay. Dr. Winckler paid a great tribute to the energy and perseverance of Dr. Heibrouner, which culminated in the establishment of a new clinic. He did not survive beyond 1914, his death being sudden; and Dr. Winckler succeeded him, becoming director of the newly built clinic of psychiatry and neurology. It had to fill a double rôle: to secure the best possible care to nervous patients, and give them the best chance of recovery; secondly, to give teaching in psychiatry and neurology. Here all patients were nursed on the ground floor; the scientific installations, laboratories for photography, Roentgen rays, etc., on the first floor, and the higher floors were used by house-doctors, administrative staff, nurses, etc. The lecture room was placed between the wards on the ground floor. He described the equipment and the plan of working by the aid of some excellent photographs. The dispensary was visited by 1,200 new patients per annum; and the lecture room had accommodation for 145 students. In the library department a special feature was the scheme

for filing ready for immediate use all the photographs, microphotographs, skiagrams, etc., taken; and for each subject there was a definite series of slides. He showed that there exists a happy spirit of co-operation with the Justiciary as well as with the other departments of the University. The average residence in the clinic was three weeks, but some patients stayed there much longer.

The President expressed the Association's gratitude to Professor Winckler for having come so far to deliver the address, and at the same time he congratulated him upon his excellent command of the English language. He had shown the high level on which psychiatry stood in Holland.

Sir FREDERICK MOTT supported the President's remarks. It had been his privilege to see the very fine institution which the Professor directs, and on his recommendation other English alienists visited it, and came back with a fund of instruction. When William of Orange rode into Leyden, after the siege, he asked the burghers whether they would have a university or a remission of taxation, and they chose a university. Sir Frederick wondered in how many English towns such a choice would be made. In conclusion he referred to the many-portal system of entry to the profession in this country, and commented on the advantage if a single State examination was operative.

### CORK MEDICAL SOCIETY.

The opening meeting of the Cork University Scientific and Medical Society (Medical Section) was held on November 6th, with Professor C. YELVERTON PEARSON in the chair. Dr. MICHAEL CAGNEY showed a case of mitral stenosis with aortic incompetence and pericardial adhesions, which was remarkable for the almost negligible rheumatic history in comparison with the extensive cardiac damage. Professor D. T. BARRY demonstrated optogram records of this case, which showed a pulsus alternans which was not appreciable by palpation of the radial pulse, and in which the appearances of the venogram suggested that regurgitation was occurring in the isometric as well as in the sphygmie period of ventricular contraction—a point of bad prognostic import. Dr. J. B. HORGAN described, with specimen and radiograms, a case of right-sided hypopharyngeal diverticulum in a male aged 32.

Professor YELVERTON PEARSON presented a case of pyometra due to a suppurating fibromyoma.

Manual removal of the placenta had been performed on the patient a year before, after a difficult labour, and at that time the obstetrician had noticed no intrauterine fibroid. On coming under Professor Pearson's care, there was great uterine enlargement, with pyrexia. A few days later some two pints of pus containing *Staphylococcus aureus* were spontaneously evacuated from the uterus, and on examination the tumour was felt blocking the internal os, where it acted as a ball valve. Panhysterectomy was performed after douching the vagina and packing the vagina and cervix with gauze. Recovery was uneventful, although previous to operation the patient's condition had been very bad.

Dr. P. KIELY demonstrated two cases of successful use of radiotherapy for rodent ulcer. In one of these cases—a large rodent ulcer involving the bridge of the nose, inner canthus of the left eye, and both lids of the right eye—considerable improvement had taken place. He emphasized the need for patience, as even in apparently hopeless cases involving deeper structures the x rays would bring about marked improvement. Dr. R. C. CUMMINS demonstrated a case of amoebic liver abscess, with partial right-sided pyopneumothorax.

THE International Congress of Comparative Pathology, which is to be held in Rome, has been postponed to the spring of 1924.

THE thirty-third French Congress of Surgery will be held in Paris on October 6th, 1924, under the presidency of Professor Tuffier. Professor Roux has been elected an honorary member. The following questions will be discussed: (1) Results of treatment of simple fracture of the neck of the femur, introduced by MM. Dujarrier and Julet. (2) Indications for surgical treatment of fibroids, introduced by MM. Robineau and Tixier. (3) Pre-operative and post-operative treatment and anaesthesia in gastro-intestinal affections, introduced by MM. Lardennois and Lambert.

## Reviews.

### DIGITALIS AND ITS USES.

THE Netherland State Institute for Pharmacotherapeutic Research, a body which resembles somewhat our Medical Research Council in some of its activities, has organized the publication of a series of monographs on important drugs; one of these on digitalis and its therapeutic uses,<sup>1</sup> published in Dutch by a group of Dutch authors, has been translated into German by Professor P. NEUKIRCH. The aim of the volume is to give practitioners and pharmacists a general account of the nature and action of digitalis and its allies, and the chemistry, the pharmacological action, and the therapeutic action of digitalis are described in turn. In the introduction a very interesting account is given of the work of the English physician Withering, the discoverer of the therapeutic action of digitalis, and an excellent portrait of him is reproduced.

In the chemical section the history of the isolation of the digitalis glucosides is related. They were isolated in an impure form nearly a hundred years ago, and since then there has been almost continuous research on this subject. The results have been very contradictory because several glucosides are present and all are relatively unstable, consequently a remarkably large number of different products have been obtained. The book gives a very clear summary of the prolonged and confusing controversies that have arisen over this question. While there is no doubt that both a water-insoluble glucoside (digitoxin) and one or more water-soluble glucosides (digitalin) can be obtained from the leaves of digitalis, the writers point out that it is not certain to what extent these substances are artefacts produced in the processes of extraction, and that it is possible that certain methods of extraction may change the water-soluble substances into the water-insoluble form. An account is given of the various pharmacopoeial preparations of digitalis, and the nature of the active principle present in each form is described. The article concludes with an interesting description of the various proprietary preparations of purified digitalis principles and the composition and relative value of these are discussed.

In the section devoted to the pharmacological action of digitalis the account of the earlier work is full, and the experiments which have been made to show the effect of digitalis on the force and duration of the ventricular contraction are described clearly. Very little, however, is said concerning the influence of digitalis on the rate of conduction of the wave of contraction in the heart, and no mention is made of any of the work of Lewis on this subject after 1911.

The chapter on the therapeutic use of digitalis similarly reveals that the authors have a conception of the action of digitalis quite different from that held in this country. In England the work of Mackenzie and Lewis has led to the belief that the action of digitalis in benefiting auricular fibrillation is of considerably greater importance than all its other actions put together. In this book, however, only a page is devoted to auricular fibrillation, and the chief question discussed is the effect of digitalis in strengthening the force of the heart's contraction in such conditions as acute pneumonia, etc. In fact, it is not unfair to say that the opinions expressed concerning the pharmacological and therapeutic actions of digitalis are nearer the opinions held in this country fifteen years ago than to those of to-day. A discussion of the relative curative values of the different pharmacopoeial preparations of digitalis reveals the fact that powdered digitalis and infusion of digitalis are the two preparations in chief use in Holland, whereas in England and America chief reliance is placed on the tincture. This difference appears to be merely the result of custom, for equally good results can be obtained with either kind of preparation. The whole is interesting in its way, but the views expressed by the writers on many points cannot be accepted; they have not taken sufficient account of the recent English and American work.

<sup>1</sup> *Die Digitalis und ihre therapeutische Anwendung*. Edited by Professors A. A. Hymans van der Borgh and R. Magnus, and Drs. C. G. Bijlsma, J. S. Meulenbelt, and M. J. Roessingh. Translated into German by Professor Dr. P. Neukirch. Berlin: Julius Springer, 1923. (Roy. 8vo, pp. 112; 32 illustrations., 1.35 dollars.)

### BLOOD PRESSURE.

DR. J. F. HALLS DALLY's manual on *High Blood Pressure: Its Variations and Control*<sup>2</sup> is intended for general practitioners who are not prepared to explore the copious scattered and to some extent inconclusive literature of the subject. It combines in a readable form a great deal of information with the results of much practical experience. With regard to the choice of a sphygmomanometer Dr. Dally says that no matter what claims are put forward by enthusiastic inventors or manufacturers of anaeroid instruments, no instrument can give such exact readings over a long period of time as a simple and accurately made mercurial sphygmomanometer. Descriptions of the various forms of instrument are illustrated and figures of their mechanisms and indications of the features that are undesirable in an instrument are given, so that such sphygmomanometers may be avoided. After reproducing tables of the blood pressures normal for various periods of life, Dr. Halls Dally gives his simple rules; thus for the ages of 20 to 60 the standard systolic pressure equals 120 plus one-fifth of the age; at the age of 60 the standard systolic pressure is 135, and for each year above this up to and including 80 add 1 mm. Hg. The relations of hyperpiesia and arterio-sclerosis are fully considered, and attention is directed to the information to be obtained from examination of the conjunctival blood vessels as a substitute for ophthalmoscopic detection of changes in the retinal vessels.

The control and treatment of high blood pressure are discussed under three headings according to the conditions present; thus the patients showing simple high blood pressure (hyperpiesia), cardio-vascular (arterio-sclerosis), and renal (nephro-sclerosis) symptoms are considered separately. Of the numerous drugs suggested for intestinal disinfection four only have seemed of value: the official thymol, the benzene derivatives dimol and benzyl benzoate, and garlic. There are special chapters dealing judiciously with the blood pressure in pulmonary tuberculosis and in relation to examinations for life assurance. The whole subject is reviewed in a thoroughly up-to-date manner, and as the book is written in an easy and interesting style it deserves, and no doubt will achieve, popularity.

### MEDICAL BIOMETRY.

THE art of statistics and the mathematical theory of probability—its first cousin—are better provided with textbooks than most branches of knowledge. It is very unlikely that anyone else will write as good a textbook of general statistics as that of Mr. Yule or a better book on probability than Professor Czuber's; but when we difference ourselves within a narrower circle and seek a good book on the specifically medical aspects of statistical methodology the case is altered. Both Sir Arthur Newsholme and Dr. Prinzing have written books which give the reader sound instruction in the data and some of the problems of the medical statistician, but both have refrained from a discussion of biometric methods. Professor Whipple went a step further and did excellent service, but there is something of the atmosphere of a railway junction about his little manual: one is hurried along and fearful of missing many important trains.

Professor RAYMOND PEARL has now entered the field. Like Mr. Yule before him, Professor Pearl has not joined the ranks of textbook writers before having placed his reputation as a first-hand investigator beyond cavil or before having learned by teaching how one must teach. We should therefore have expected him to produce a good textbook, and we have not been disappointed.<sup>3</sup> He is under no illusions whatever as to the probable mathematical knowledge of his public, whom he neither perplexes with algebra nor treats with an exasperating condescension. Professor Pearl approaches the subject by the historical route. He first shows what the pioneers aimed

NINETY-SECOND ANNUAL MEETING

of the

British Medical Association,

BRADFORD, 1924.

THE ninety-second Annual Meeting of the British Medical Association will be held at Bradford next summer, under the presidency of Mr. J. Basil Hall, M.Ch.Chancab, consulting surgeon to the Royal Infirmary, Bradford, for scientific and clinical work will be held, as usual, on the three following days, the mornings being given up to discussions and the reading of papers, and the afternoons to clinical and laboratory demonstrations. The Annual Representative Meeting will begin on the previous Friday, July 18th. The provisional programme for the work of the twelve scientific sections is being drawn up by an Arrangements Committee, consisting partly of Bradford representatives and partly of members elected by the Council. The names of the presidents of sections were given in a Current Note published in last week's SUPPLEMENT, and the full list of officers, together with other details of the arrangements for the Annual Meeting, will appear in subsequent issues. On the last day of the meeting—Saturday, July 26th—there will be excursions to places of interest in the neighbourhood. We publish below the first of a series of descriptive and historical articles on Bradford.

BRADFORD: AN HISTORICAL SKETCH.

J. HAMBLEY ROWE, M.B., C.M.

FELLOW OF THE SOCIETY OF GYNECOLOGISTS.

persisted in the Yorkshire dales to within the last few years. Certain dialect words explainable only by Celtic roots occur, such as to *foest* (the prising up of curdled milk by an infant), *sad* (that is, solid, firm—as in sad cake), *brat* (an apron), *boggart* (a bogey, hobgoblin). A few place names of Celtic origin survive, such as Pennington, Pimhow, Penmythorn, and Cam Fell, the names of hills. In respect to folk-lore we still meet with the courage,

which has been explained as a survival of a phase of maternal archy and therefore of pre-Celtic and non-Aryan days. In Niddedale the souls of unbaptized infants of unbaptized infants bodied in that strange bird, the night-jar. Infants that are bad and often screaming are often screaming and wakeful when their parents want to sleep, and the selection of the night-jar as a receptacle appears extremely appropriate.

The Roman occupation coincides pretty nearly with the last phase of Celticism in Yorkshire. Though no Roman road has yet been proved to have passed through Bradford, near the south-west corner of the city wall marked traces of the Roman road from Manchester to Borooughbridge (Insaurum) via Ilkley are yet to be seen. At Ilkley there was a Roman camp of some pretensions which was partly excavated in 1921 and 1922. Numerous remains of buildings, ware, coins, and altars have been found. Another Roman road from Ribblesdale to Tadcaster and York also comes through Ilkley, and a fort on this route has been excavated at Elslack near Skipton. That the Saxons colonized the West Riding very thoroughly is indicated by the great majority of the place names, amongst which those ending in *ton* and *ley* predominate, whilst *ford*, *shar*, and *worth* are very frequent terminations. There are crosses of this age in Ilkley

Bradford Church is the City Wall, 1613.

Showing packs of wool on towers preceding it from bulks and cannot balls. Bradford Church is the City Wall, 1613. It is on the moorlands that we find numerous evidences of Neolithic man in flint implements, barrows, stone circles, and notably cup and ring marks. Indeed, two examples of urn burials have been discovered within the city boundary. In the upper reaches of the Aire and the adjoining Wharfe many important remains of early man have been found, and just over the watersheds of these rivers is the famous Victoria Cave at Settle, which yielded to Professor Boyd Dawkins a wealth of prehistoric remains. Of the Brigantes who inhabited this part of England few traces are to be found. Perhaps the most interesting is the method of scoring sheep in corrupt Celtic enumeration which

at and then describes practically the methods by which modern biometricians can solve at least some of the problems which our predecessors dreamed of solving. Medical men have complained that the delectable city of the statistician is surrounded by a barbed wire entanglement of algebra and that the usual welcome accorded a visitor who attempts to creep under the wire is a shower of bombs discharging gamma functions, determinants, and other poisonous gases. Professor Pearl has cut a path through the wire and provided gas masks. That some of the denizens of the city will be able altogether to refrain from bombing the visitors, and that the gas masks will be entirely impervious to the fumes, are propositions we are not prepared to maintain. We can see, in the mind's eye, hands reaching out to the store of bombs when sundry philosophers chance on Professor Pearl's calculation of the probability that the sun will rise to-morrow. The terrible spectre of "spurious correlation" which haunts all those who have to correlate rates may squeak and gibber over the interpretation of such examples as that of page 329. For our part, however, we think Professor Pearl entirely justified in refraining from highly technical discussions. Without courage one arrives nowhere. No medical man could read this book without learning a great deal, very few could read it without becoming interested in the subject. In other words, Professor Pearl has succeeded, and we congratulate him heartily.

### PSYCHO-ANALYSIS.

#### *A Critique of Psycho-analysis.*

Dr. JOHN T. MACCURDY has written a book entitled *Problems in Dynamic Psychology*,<sup>4</sup> in which he subjects the theories of Freud to a critical discussion. The author differs from most critics of Freud in that he is himself a professed Freudian, and has had considerable experience of psycho-analysis from the practical standpoint. He has discovered from the study of Freud's writings and from his own observations certain limitations and inconsistencies in psycho-analytic formulations, and he feels that the greatest service which can be done to psycho-analysis to-day, and the most practical form for tribute of gratitude to Freud to take, is the dispassionate criticism of his work.

In the first part of the book the author deals critically with Freud's views on the unconscious, instinct, sex, repression, and ego-libido, dementia praecox and paranoia, depression, the neuroses, emotions, and dreams. The work of two other psycho-analytic writers, Ferenczi and Burrows, is also discussed in a section dealing with the preconscious phase of development. These discussions presuppose an intimate knowledge of the intricate details of psycho-analytic theory, and the writer's arguments will only appeal to those readers who are versed in Freud's terminology and to whom it conveys a meaning. The ordinary reader will find Dr. MacCurdy's criticisms difficult to understand, and we could have wished that he had done more to clarify the obscurities of Freud's teaching. A lengthy chapter is devoted to a criticism of the theories of the late Dr. W. H. R. Rivers as outlined in his book on *Instinct and the Unconscious*. The author's criticisms are almost wholly adverse, but he, nevertheless, regards this book as extremely valuable in its suggestiveness, and thinks that it may prove to be a landmark in the evolution of psychopathology. Dr. MacCurdy's own views are given in the concluding chapters, which are thus constructive rather than critical. He is dissatisfied with the exclusive importance attached by Freud to the sexual as an explanation of practically all psychopathological phenomena, and his experience has led him to the view that any general formulations must include the factors of social and ego-instincts as well as sexual. Dr. MacCurdy's studies of these instinctive tendencies and their interactions are of value and interest, and include a number of observations which the psychopathologist will find helpful.

<sup>4</sup> *Problems in Dynamic Psychology: A Critique of Psychoanalysis and Suggested Formulations.* By John T. MacCurdy, M.D. Cambridge: The University Press; New York: The Macmillan Co. 1923. (Cr. 8vo, Pp. xv + 323, 12s. 6d. net.)

### Group Psychology.

In a book the English translation of which has the title *Group Psychology and the Analysis of the Ego*,<sup>5</sup> Professor SIGMUND FREUD subjects the theories of Le Bon, MacDougall, and Trotter on the psychology of the crowd and the herd instinct to a critical examination. An interesting feature of the book is that it contains a clear statement of what the author means by libido or sexual energy. He writes as follows:

"We call by that name (libido) the energy of those instincts which have to do with all that may be comprised under the term 'love.' The nucleus of what we mean by love naturally consists (and this is what is commonly called love, and what the poets sing of) in sexual love with sexual union as its aim. But we do not separate from this on the one hand, self-love, and on the other, love for parents and children, friendship and love of humanity in general, and also devotion to concrete objects and to abstract ideas."

From this wide conception of libido or sexual energy—so wide as obviously to embrace the whole field of emotional attraction—Freud proceeds to develop the view that love relationships (or, to use a more neutral expression, emotional ties) constitute the essence of the group mind. He combats the view that the "social" or "herd instinct" is an irreducible and primitive one, and endeavours to show that it is possible to discover the beginnings of its development in the emotional ties of the family group. The study of the affective relationships between one person and another leads the author into a discussion as to the nature of hypnosis from the standpoint of psycho-analytic theory. He also gives a complex analysis of the process of "identification," and illustrates the importance he attaches to this process by examples taken from morbid mental states, especially some forms of melancholia. The book contains some of Freud's most recent views and is of interest on that account.

### Psychotherapy.

Three lectures delivered by Dr. WILLIAM BROWN at King's College, London, have been published in a small book entitled *Talks on Psychotherapy*.<sup>6</sup> The first lecture deals with dissociation, hypnotism, and suggestion; the second with psycho-analysis, abreaction and transference, and the modern development of the libido theory; and the third with Freud's recent views on the psychology of melancholia, auto-suggestion, and the will. Certain obscure passages are included in the first lecture, where the author considers the relation between mental and spiritual healing. A distinction is here drawn between mind and spirit, and Dr. Brown does not make it clear whether he means by the latter term a creative life principle or a mystical essence which is part of an external spiritual power. In the former sense the word "spirit" might be legitimately used in psychology; it merely implies that life and mind are creative rather than mechanistic, and there are a number of facts in regard to the behaviour of living organisms which might be held to justify the erection of a psychology on a non-mechanistic basis. In the latter sense, however, the word "spirit" would seem to be out of place in psychological nomenclature; it is not a concept based upon the observation of facts; rather is it one derived from certain feelings, experienced by individuals at moments of mystic insight, of being one with an ultimate spiritual reality. The introduction of this definitely religious concept into psychological theory and practice would appear to be an innovation of doubtful value. The book as a whole, however, is clear, readable, and interesting, though it naturally only touches the fringe of the subjects considered by the author.

### HEREDITY AND EUGENICS.

THE greatest obstacle in the way of an author who compiles a treatise on heredity is to avoid both the dullness of a catalogue and the minute detail of a memoir, or rather a collection of memoirs. Professor GATES<sup>7</sup> in his book on

<sup>5</sup> *Group Psychology and the Analysis of the Ego.* By Sigm. Freud, M.D., LL.D. Authorized translation by James Strachey. London and Vienna: The International Psycho-Analytical Press; London: G. Allen and Unwin, Ltd. 1922. (Roy. 8vo, pp. 334, 7s. 6d. net.)

<sup>6</sup> *Talks on Psychotherapy.* By William Brown, M.A., M.D. (Oxon.). D.Sc., M.R.C.P. (Lond.). London: University of London Press, Ltd. 1923. (Cr. 8vo, Pp. 65, 2s. 6d. net.)

<sup>7</sup> *Heredity and Eugenics.* By R. Ruggles Gates, Ph.D., F.L.S. London: Constable and Co. 1923. (Demy 8vo, pp. x + 288; 33 figures. 21s. net.)

"time-honoured Lancaster," succeeded to this estate, and a singular tenure of land was granted by him to John Northrop of Manningham. On the many occasions that the Duke of Lancaster passed through Bradford, Northrop "was on the blowing of a horn (*Urum flatum cornu*) to wait upon the Duke with a lance and hounding dog for forty days and to have for yeoman's board one penny for himself and a halfpenny for the dog." A descendant of Northrop granted land to one Rushforth on condition that he held the lance whilst Northrop's man blew the horn. The horn is still preserved and is now in the possession of the Corporation.

A high-contrast, black and white photograph of a large, multi-story building, likely a government or institutional structure, viewed from a low angle. The building features numerous windows and a prominent central section. The image is heavily degraded with significant noise and artifacts, including a large dark diagonal streak across the upper left portion.

The incursion of the Scandian and Danish races and their settlement in Bradforddale and Airedale is also indicated by the not infrequent terminations in place names of *thwaite* and *gill* (Norse) and *by* and *thorpe* (Danish). The dialect of the district also affords evidence of the influence of these peoples. A child is said to *laxe* when it plays, or to *lidge* instead of shrike or screech. To *littie* means to tickle or to *lig* down means to lie down, *neve* is a hat, and a bridge is yet a *brigg*, and to *skift* is to shift. This shows that the Norse influence was sufficiently strong to resist the palatalization of the guttural.

In the Domesday Survey of 1086 we first find the town mentioned as the manor of Bradford, together with six unnamed berewicks attached to it which were in the possession of Gamel, *Tempus Regis Edwardi*. The description of Bradford, like many another Yorkshire Domesday manor, finishes with the words, *It is waste*. Four years after the battle of Hastings the Conqueror came north to crush a rebellion.

*Heredity and Eugenics* has not altogether avoided the former danger; it cannot, indeed, be avoided in a volume of 250 pages without devoting disproportionate attention to some one phase of the subject or line of research. His book is a useful guide to the literature, for its plan is to recapitulate briefly the conclusions of the authors cited and to indicate some of the difficulties of interpretation. The logician will probably think that in many instances the evidence that the traits considered are inherited is incomplete, since it amounts to no more than the statement that in certain pedigrees such or such a character recurred in several generations. The evidential value of these concurrences depends on the assumption that the characters considered occur so infrequently that their independent existence in several members of one stock is an improbable event, less probable than that a common organic factor was responsible. In some of the cases the alternative may be accepted without further evidence, but not in all. Again, in instances of purely functional traits, the factor of common environment cannot be ignored.

Professor Gates justly points out that various effusions of psychopathologists—usually, we think, the less intelligent followers of the psycho-analytic cult—"frequently fail to appreciate that any element of mental inheritance exists." He instances the lucubrations of Kempf, who seeks to explain the development of Darwin's genius on psycho-analytic lines and descants on his mother-fixation and other such topics. As Professor Gates remarks, "it ought to be obvious that if Darwin had been a person of mediocre ability, neither his mother attachment nor anything else could make of him a great naturalist." This is one of the obvious facts that some psychologists are constantly overlooking.

Professor Gates has written a useful book which, we think, will be valuable to the busy medical man who has no time to consult the enormous literature of the subject.

### NOTES ON BOOKS.

THE series of *Optotypes* by GREEN and EWING<sup>1</sup> present some new features; much of the work on the series was done in 1915 before the death of Dr. Green. The types embody the fundamental theory and classical notation of Snellen; the variations are conceived with a view to eliminate unequal ratios of gradation, by adopting a gradation in geometrical progression—that is, 1, 2, 4, 8, 16, 32, 64; to simplify the routine and to enlarge the scope of trustworthy clinical determinations by providing varied sequences and arrangements of the letters and of other characters; and to minimize the differences in the legibility of the several test letters through a conservative change of the typographical character. The letters are printed in block capitals on each side of the cards, and the pictographs for illiterates are treated similarly; the pictures are simple and show such common objects as a teapot, a jug, a cross, a square, and a circle. It would be a good plan to print these optotypes and the pictographs on long vertical cards, which could be conveniently placed in the trial drum in general use; for rapid testing a series of thirty-five plates is rather a large one to juggle with; the letters are certainly very good and legible, and if the surgeon is concerned for any reason to determine the maximal acuity of any case, they will be found useful and trustworthy; we have got 6/4 quite easily with them.

Mr. J. T. HACKETT has enjoyed the uncommon pleasure of seeing his *Commonplace Book* put into print. The first edition was published in Adelaide in 1919; the first edition published in England appeared, we gather, in the same year, the second and third in 1920, so that the book pleased the public; the fourth edition,<sup>2</sup> larger than the first, has been issued this autumn. The extracts, which show wide reading and catholic taste, have been thrown together without any order, a want of method the author justifies on the ground that it introduces the element of surprise. Two observations suggest themselves. The first is that the beauty of verse must depend in part on the cadence produced by the mere choice and order of words, for in some of the most beautiful lines in the English language the thought is neither very profound nor very original. The other is that the eighteenth century knew better how to pack much matter into few words

than any English writer of to-day or for many days. Pope, for example, as some of Mr. Hackett's extracts show, could sometimes equal the polished gems of the French epigrammatists. The author has inserted a number of explanatory notes, and also a few longer commentaries which are not quite so appropriate.

The *Medical Directory*<sup>3</sup> for 1924 has been issued, and the reviewer may well wonder what he can find to say new about an annual which has so thoroughly established itself in the esteem of the profession. It contains 1,297 more names and 26 more pages than the issue for last year. We welcome the list of honorary secretaries of Local Medical and Panel Committees, which now seems to have become a standing feature, but regret the continued absence of the summary of laws affecting the medical profession. Long experience has enabled the editors to make the volume as nearly perfect as a yearbook in this changing world can be. From the table showing the numbers of the profession year by year since 1915 it appears that there are now rather more registered practitioners resident abroad (7,648) than in London (7,233); this is the third year in succession in which this phenomenon has presented itself, but the list of practitioners beyond the seas does not include those who hold degrees from Dominion universities but have not taken diplomas or degrees in the home countries. The number of practitioners in the provinces of England, in Wales, Scotland, and in Ireland, all show small increases; in fact the only decrease is in the Services—Navy, Army, Air Force, and Indian—and even there the decrease is small, from 3,453 to 3,452. In the *Directory* for 1914 the number was 3,356.

Messrs. John Wright and Sons, Ltd., of Bristol, have sent us a copy of one of their visiting lists—*Wright's Improved Physicians' and Surgeons' and Consultants' Visiting List*, arranged by Mr. ROBERT SIMPSON, L.R.C.P., L.R.C.S. The lists are made in six sizes to accommodate the names of from 40 to 240 patients each month. By means of an ingenious system of half-page interleaving patients' names need only be entered once a month, thus economizing the practitioner's time. A number of useful tables have been incorporated in the book, together with much valuable information, a consultant's record, and space for notes and cash accounts. The visiting list is not much larger than an ordinary pocket-book; it is a very handy and useful little volume. The prices range from 10s. 6d. to 13s.

### PREPARATIONS AND APPLIANCES.

#### *Oleo-Bi.*

It was generally thought that the organic compounds of arsenic of the type introduced by Ehrlich were specific in their effect on the *Spironema pallidum*. Slowly it became clearly apparent that this assumption must be abandoned. Other metallic compounds have been found to possess similar efficacy, and there is now no doubt that the discoveries of Ehrlich did no more than open the gate to a rich field for exploration. In this connexion bismuth has attracted particular attention, and the remarkable fact has emerged that effective results are obtained from very simple compounds. Acting on decisive successes obtained with these the Hoffmann-La Roche Chemical Works (7, Idol Lane, London, E.C.3) have engaged in the manufacture of two such preparations, named *Oleo-Bi* and *Tarto-Bi*. The former consists of a suspension of bismuth oleate in oil, and the latter is an aqueous solution of sodium bismuthyl tartrate, a substance of analogous constitution to tartar emetic. A specimen of the *Oleo-Bi* submitted to us has been examined analytically with satisfactory results as to the chemical purity and the quality and permanence of the emulsion.

#### *A New Michel Clip Remover.*

Dr. Frank H. Edwards (Shrewsbury) writes: I have often wished that there were a simple way of removing Michel clips, as the two methods commonly used have great disadvantages. In one the under blade of a special pair of forceps has to be forced up against the actual wound; in the other, where two hooks are used, the method is clumsy and the hooks are not easy to manipulate. I have designed a pair of forceps angled twice on the flat with two points instead of blades, one point being 1/16 in. longer than the other. These points are separated by

closing the handles and are normally held together by a strong spring. The method of use is to insert the longer point into an eye of the clip, and while this point is steadied the shorter one can easily be fitted into the other eye. The handles are then closed and the clip is stretched out flat, being then easily removed. There is no discomfort to the patient and the forceps are very easy to use. Messrs. Mayer and Phelps have made the above instrument for me.

<sup>1</sup> *Optotypes: Consisting of Test-Letters and Pictographs for Measuring the Acuteness of Vision.* By John Green, M.D., LL.D., and A. E. Ewing, A.M., M.D. London: Henry Kimpton, 1923. (Med. 8vo, pp. 24; 19 cards containing letters, tests, etc. 25s. net.)

<sup>2</sup> *My Commonplace Book.* By J. T. Hackett. Fourth edition. London: Macmillan and Co., Ltd. 1923. (Demy 8vo, pp. xx+433; 12s. 6d. net.)

Up to within the last 150 years the work was carried on in cottages and in some cases houses all over the countryside. The farmers, millers were built, until in 1819 the aggregate of horse-power amounted to 152, all built in the face of severe opposition. At Heckmondwike, in the neighbouring Speen Valley, in April, 1812, the Luddites (a mob calling themselves the army of General Ludd) attacked Rawfolds Mill and caused

much damage. Several of the rioters were tried at York Assizes and received punishment. Charlotte Brontë, in her novel *Shirley*, incorporated many of the incidents in her account of the riot at Hollows Mill. A year or two ago these incidents were cleverly filmed at the exact place of their occurrence. Since those troublous days Bradford has expanded by leaps and bounds in spite of strikes, breaking of banks, imposition of tariffs, and other hindrances to trade development.

Several causes have contributed to the rapid expansion of the town: (1) The proximity of coal and iron deposits and their development by the Low Moor and Bowling Companies; (2) the erection in the early decades of the last century of many weaving and spinning mills equipped with machinery which drew country folk in great numbers to the town—a people, too, who could and would work; (3) the presence of suitable building stone in an inexhaustible quantity in the neighbourhood; and (4) the fact that the air of Bradford possesses just that degree of humidity which enables the spinning of wool to be perfectly effected. It is said that in no other part of England or of the world can wool be spun so easily and efficiently as in Bradford. This is probably due to the fact that the town lies in the hollow of a tarry valley of Airedale, and that the town being that hollow is in most places not much more than 9 inches deep, while below it is an extensive deposit of glacier-borne boulder clay which is more or less impervious.

Bedroom in which the ghost appeared to the Earl of Newcastle.

## PROFESSORSHIPS OF THE ROYAL SOCIETY.

RESIDENT'S ANNUAL ADDRESS.

Necessary meeting of the Royal Society on November 10th, 1933, at 11 o'clock, was held in the President's room, Sir CHARLES SUMNER, G.B.E., President, presiding. The Society's policy in respect of the various funds at its disposal for the support of research. He prefaced his remarks on this subject by referring to the fact that the Society had been fortunate in securing the services of Sir Alfred Tarrow, who had been elected to the office of President in 1932. He then proceeded to discuss the various funds at the Society's disposal, and the policy of the Society in respect of their use. He pointed out that the Society had a large number of funds, and that it was his duty to ensure that these funds were used in the most effective manner possible. He then discussed the various funds in detail, and the policy of the Society in respect of their use. He pointed out that the Society had a large number of funds, and that it was his duty to ensure that these funds were used in the most effective manner possible. He then discussed the various funds in detail, and the policy of the Society in respect of their use.

advancing discovery was the creation of a greater opportunity for fully experienced investigators of already proved first-rate capacity in research. It was felt that increased opportunity afforded to such investigators was likely, with a prospect of comparative certainty, to attain its recompense in the achievements such investigators would accomplish. The Society, by virtue of its own organization, had the opportunity of knowing the powers and scientific circumstances of representatives of this class of investigator. Over an ample field, and at many points in that field, it lived in contact with their endeavours, was conversant with work they had already done and often with work they were in fact prosecuting and could prosecute more fully. In institutions, university or other, such investigators for the most part occupied positions to which opportunity for research was an adjunct to calls of other nature upon their strength and time. Such seats of learning showed themselves in instance after instance desirous that their personnel should prosecute research, but also, in instance after instance, were embarrassed to secure to them adequate time for so doing. Therefore it was felt that the Society, by securing, in co-operation with this or that particular institution, ample freedom of time for a distinguished member of the staff to prosecute research undividedly, would be helping the

**BLACKWATER FEVER:****ITS ETIOLOGY AND PARASITOLOGY.**

IN our last issue we referred briefly to the recent research activities of the London School of Tropical Medicine. During the past two years Dr. J. Gordon Thomson, Director of the Department of Protozoology of the School, has been engaged upon an inquiry into the etiology of blackwater fever in Southern Rhodesia, and his preliminary report has just been issued.

In all parts of the world where pernicious malaria is rife blackwater fever is known, while it does not occur where there is only the benign tertian type of malaria. Although this is presumptive evidence that pernicious malaria (*P. falciparum*) is associated with blackwater or haemoglobinuric fever, yet many clinicians and not a few investigators have been attracted to the hypothesis that there is a special protozoan or spirochaetal parasite. The most recent and apparently convincing evidence in this direction was the work of Blanchard and Lefrou, who by a special technique claimed to have demonstrated a new spirochaete, named by them *Spirochaeta biliohaemoglobinuriae*. In an earlier communication\* from South Africa

MONTHLY INCIDENCE OF MALARIA AND BLACKWATER FEVER, SOUTHERN RHODESIA.

Hospital admissions 1913 to 1922 inclusive.

—●— Malarial curve.

- - - - - Blackwater fever curve (this curve is multiplied by 100).

Total malaria treated in hospitals, 6,608.

Total blackwater fever treated in hospitals, 492.

Dr. J. G. Thomson conclusively showed by the study of a series of fifteen cases from the first day of illness to its termination that true spirochaetes did not occur, but that the Blanchard-Lefrou technique gave what he has termed "pseudo-spirochaetes"—that is, artefacts or filaments showing Brownian movement and resembling spirochaetes. These non-living pseudo-spirochaetes could also be recovered by the same technique from cases of malarial anaemia and from the blood of cattle with piroplasmiasis.

In his new preliminary report† Dr. Thomson frankly adopts the view that blackwater fever is due to infection with the malignant tertian malaria, which gives rise to 96 per cent. of the malaria cases in Rhodesia, and is of the same morphology as in Panama and Macedonia, although there are variations in individual infections. The close monthly relationship in the rise and fall of these two diseases is shown in the striking chart here

reproduced of the admissions to the hospitals of Southern Rhodesia for the past ten years of 6,608 cases, and 492 cases of blackwater fever.

In discussing this chart Dr. Thomson makes the following observations:

By making an analysis of the hospital statistics of Southern Rhodesia for ten years (1913 to 1922 inclusive) I have been able to represent graphically the monthly relationship between malaria and haemoglobinuric fever. This chart shows clearly that as the incidence of malaria rises the cases of blackwater increase, and as the malaria falls we have a corresponding diminution of blackwater fever.

The cases of malaria commence with the first rains at the onset of summer in October, and steadily increase during November, December, January, February, and March, finally reaching a maximum in April. The first and last three months of every year supply the rainfall and ideal temperature required for the rapid multiplication of anopheline mosquitos. Observations and collections of anopheline mosquitos showed that these were most numerous during the month of April. . . .

It will be noted that the worst months for blackwater fever are April, May, and June, as it is during these months the full effects of malaria occur, and the sudden drop in the incidence of blackwater during the months of July, August, and September corresponds in a remarkable manner to the diminution of malaria and the disappearance of mosquitos.

Such a co-relationship as indicated by this chart over a period of ten years, which includes 6,608 cases of malaria and a total of 492 cases of blackwater fever, shows definitely that malaria and haemoglobinuric fever are either one and the same disease or that both diseases are conveyed by the same biting insect or by insects with similar seasonal and domestic habits.

The fact that blackwater fever occurs principally amongst persons who live in unprotected houses and are careless about mosquito nets gives us positive evidence that this condition is associated with the bites of mosquitos, and reference to the chart proves that it is undoubtedly associated with the period when anopheline mosquitos are most active. It is important to note that a temperature of over 61° F. is necessary for the successful development of the sexual cycle in the anopheline female, and . . . in October, November, December, January, February, and March the mean minimum temperature never falls to 61° F., and therefore ideal conditions exist for the rapid production of infected mosquitos during these months.

It is well known that malaria parasites generally disappear from the peripheral blood after the onset of blackwater, and this has been regarded by some as evidence that the disease cannot be due to the malaria parasite. Dr. Thomson was so fortunate during his inquiry as to examine 23 cases prior to the onset of blackwater symptoms, and in every case was able to demonstrate the presence of malaria parasites, although these disappeared with or shortly following the commencement of haemoglobinuria. He recognizes a condition named the "pre-blackwater fever type"; in it a small dose of quinine will actually precipitate haemoglobinuria, and it develops in patients suffering from chronic malaria who take quinine irregularly and inefficiently. While quinine will cure malaria and so prevent blackwater it is useless to attempt to cure malaria with a few doses of quinine given once a week or fortnight, for this only results in chronic malaria, and so in a highly dangerous condition which may culminate in blackwater fever.

A study of the anopheline mosquitos of Rhodesia implicates *Anopheles costalis* as the chief carrier of malaria. This mosquito abounds all over Southern Rhodesia, is wild in its nature and avoids large towns, but breeds in pools of water in the veld and in the margins of slowly flowing spruits. It is, therefore, a problem of grave complexity and menace for the new Government of Southern Rhodesia. Happily the publication of Dr. Thomson's report among the earliest of the White Papers laid before the Legislative Council is a good augury that those undertaking the new administrative responsibilities are alive to the wisdom of early efforts to ameliorate the health conditions of the newest anapage of the Crown.

\* The Common Occurrence of Pseudo-spirochaetes in the Blood of Blackwater Fever Cases and of Normal Human Beings and Animals when using the Technique of Blanchard and Lefrou. *Journal of Tropical Medicine and Hygiene*, August 1st, 1923.

† Preliminary Report on the Results of Investigations into the Causation of Blackwater Fever in Southern Rhodesia. By J. G. Thomson, M.B., Ch.B. Presented to the Legislative Council of Rhodesia, 1923. Salisbury: Printed by the Government Printer.

quarrying the prize with their two collaborators, Dr. and Professor Collip. The furtherance of a scientific inquiry by organized collaborators on a wider scale, yet mounting in fact to team work, was exemplified by the award of the Nobel prize for medicine for 1923 to Dr. A. V. Hill, of University College, London, was ungratifying to physiologists. Professor Hill's investigations dealing with the thermodynamical processes underlying muscular contraction, enabling contraction to long occupied and taxed the powers of many physiologists, was as far-reaching in outlook as it has mastery in conception and execution. The President then presented the Society's among them was a Royal Medal presented to Dr. C. J. Martin, Director of the Lister Institute. President said:

"Professor Martin is distinguished for contributions both to physiology and to pathology. Investigating worms he differentiated two groups in virtue of action—one nervous, the other, so to say, humoral work on heart regulation in monotonous three lig the evolution of the thermotaxis of warm-blooded More recently his researches have lain in the chemistry of proteins, and in protein metabolism. A of experiments carried out by him in collaboration his colleague, Mr. Robison, on the minimum nitrogen penditure of man and the biological values of several kinds of protein-food, stands as one of the most valuable contributions yet made to a subject as difficult as important. Besides these personal researches at first Professor Martin has influenced inspiring the research in medicine in this country. He was a member of the Plague Commission which organized the research finally determining the mode of transmission of the on antityphoid inoculation. As director of the War Office Institute he has contributed to many investigations in addition to those actually issued in his name. There has been intimately associated with the inquiry in the influence of accessory food factors of diet in the prevalence of 'deficiency' diseases, such as beriberi and rickets, an inquiry the success of which may be regarded as one of the recent triumphs of preventive medicine. His abilities have been ever at the call of his colleagues, and in the most public-spirited way he has served the community in general."

engaged in class instruction. The President referred to the appointment of Professor E. H. Starling just a year ago to be Rounton Professor, and announced that two Xarow professors had been awarded—one to Professor Alfred Fowler, F.R.S. (Royal College of Science, South Kensington), the other to Mr. G. I. Taylor, F.R.S. (Cambridge). Professor Fowler was well known in the world over as a spectroscopist whose researches had been of the greatest value to astronomy, to physics, and to chemistry. Professor Taylor had started his scientific life as an applied mathematician and had proceeded from abstract hydrodynamics to practical problems of geophysics and meteorology. The record of both gave every justification for hoping that in the unfettered freedom of the Xarow professorships they would find opportunity for still ampler fulfilment of brilliant work. It was fortunate that both would continue their researches in the laboratories from which their outstanding work had issued in the past, and of whose tradition indeed their reputations already formed a part.

The Council had not thought fit to insist that the professors should either teach or not teach; the sole condition laid down was that to research their main energies should be devoted. Sprat, the first historian of the Royal Society, recorded that to Bacon's *Advancement of Learning* much of the inspiration for the inception of the Society and for its early life was due. Bacon had dreamed of "a college for the obtaining of knowledge of the causes of things" and enumerated its grounds and apartments, its Fellows and their functions. "Of its Fellows," he said, "twelve there be that sail in foreign countries to bring patterns of experiments from all other parts. These we call merchants of light. Then three we have that collect the experiments which are in all books. These we call deprecators. . . . And," he continued, "on our foundation we have three Fellows who all their days try new experiments such as themselves think good. To-day, on the completion of its two hundred and sixty-first year of existence, the Society found itself able to fulfil closely this particular of Bacon's enthusiastic imagining. Three Fellows on its Foundation were to "try all their days new experiments such as themselves think good." They might well be designated in Bacon's word "pioneers."

Alumni of the Society had received it with hope that the funds already in hand would prove but the auspicious starting-point for yet others of similar distinction, and that either the Royal Society or other bodies might have it in their power to endow the research of all those individuals whose life ought, in the best interests of the community, to be devoted to scientific research as the main purpose of their life-career.

At the previous anniversary, the President continued, he had adverted to the high promise implied in the discovery of insulin; that promise had in the elapsed twelve months proceeded satisfactorily towards further fulfilment. It would seem possible that under treatment by insulin the beta-cells of the pancreatic islets might be able to re-establish permanently their functional powers, and that in certain cases the treatment might produce not only temporary, but lasting relief from the diseased condition. All the more welcome, therefore, was the recognition of their work received by Dr. Banting and Professor Macleod by the award of the Nobel Prize for medicine for 1922. The success of their work was based on intimate co-operation between physiology and biochemistry—indeed these cognate studies could be considered separate—and the success of their research early in its progress was an instance of the value of team work in the best sense of the word.

## British Medical Journal.

SATURDAY, DECEMBER 8TH, 1923.

### THE LIMITATION OF PHYSIOLOGICAL STANDARDIZATION.

IN a lecture delivered recently to the Pharmaceutical Society Mr. H. A. D. Jowett, D.Sc., of the Wellcome Chemical Works, who has had long experience in the manufacture of drugs which can at present only be standardized by the physiological method, emphasized the fact that the method is inherently inaccurate and therefore unsatisfactory. It should be regarded merely as a stopgap, and researches pushed forward to discover satisfactory ways of isolating pure chemical bodies. Nevertheless physiological standardization is a great advance on no standardization at all, and is usually accurate within 20 per cent. This margin of error is wide, but the drugs to which it is applied are in the main those whose active principles are so unstable that they have not yet been isolated or estimated quantitatively, so that but for physiological standardization there would be no guarantee that the finished product, made from the raw material of such drugs, would have any therapeutic activity whatever. The chief drugs which require physiological standardization are ergot, the digitalis group, pituitary extract, insulin, and the organic arsenicals. Of these the first is a rather special case; in it standardization is especially unsatisfactory because it contains a variety of active principles, and it has not yet been decided which is of chief therapeutic importance. Under such conditions no form of standardization can be of any great value, so that the unsatisfactory state of affairs as regards ergot cannot be attributed to the methods used, since the position would not, for the reason given, be materially improved did we possess exact chemical means of standardization for every constituent in the crude drug.

The chief objection to physiological standardization in the other cases is its inherent inaccuracy; there are numerous reasons for this. One is that if intact animals are used the worker is at the mercy of variations among individual animals, for living animals refuse to be standardized. This difficulty can only be evaded by using very large numbers of animals; not only is this very expensive, but there remains the problem of seasonal variations in susceptibility. On the other hand, if isolated organs are used the least variation in technique may produce enormous errors. Another difficulty is to establish some unvarying standard with which to compare the drugs tested. In the case of digitalis ouabain is used, but unfortunately it is very difficult to obtain. A non-variable standard pituitary preparation has not yet been put on the market, although hopes are expressed that such a preparation may soon be forthcoming.

The outbreak of war cut off the former German supplies of the arsenobenzol group of compounds, and the results of any undue toxicity in these drugs would have been so serious that the Board of Trade, before allowing any batches manufactured in this country to be sold, determined that they must be submitted to biological tests. The establishment of a suitable toxicity test was very difficult. With novarsenobenzol a fresh difficulty arose; a product was obtained which, though of very low toxicity, had also

a very low curative power. This led to the establishment of a therapeutic test, and now the products have to satisfy biological tests for undue toxicity and for satisfactory therapeutic potency. The present position, as summarized by Dr. Jowett, is that while the biological test undoubtedly eliminates any product having an undue degree of toxicity or of low curative efficiency, yet it is possible that some batches just as good as those passed are rejected owing to variations in the animals used. The manufacturer has to face the awkward situation that the drug he produces must satisfy tests which have a possible error of about 30 per cent. Dr. Jowett mentions one instance in which, when two samples of the same batch of novarsenobenzol were submitted, one sample was passed and the other rejected. Nevertheless he concludes that, despite these limitations and the accident of experimental error, the biological control of these potent remedies is most desirable; it should, however, be recognized that manufacturers are put to serious inconvenience and expense, in the first place by not feeling confident whether their preparations will be passed either by their own or the official biologists, and secondly, by finding that improvements in the process are rendered difficult. It has been pointed out that a more accurate method of testing is highly desirable, as the losses caused by an error of testing in the case of such costly material as insulin may be considerable. While there is no need to feel alarm about the efficiency of physiological standardization it is necessary to guard against the assumption that it has a greater degree of accuracy than it actually possesses. The limitations of the method emphasize the importance of replacing it as soon as possible either by chemical methods, if satisfactory ones can be produced, or, better still, by the employment of the pure active principles.

This is a very fair summary of the situation from the manufacturer's point of view. Medical men will naturally emphasize the point that some form of standardization is essential for all potent drugs, and that most particularly it is necessary in those cases where the active principles are so unstable that they cannot be isolated quantitatively. Obviously it is in these cases that there is the greatest danger of obtaining inactive products, and it is in them that physiological standardization is employed.

Physiological standards have been adopted in the *United States Pharmacopoeia* in the case of cannabidiol, aconite, digitalis, strophanthus, squills, adrenaline, pituitary extracts, and antitoxic serums. A conference was held at Edinburgh this summer under the auspices of the League of Nations, at which all the chief countries of the world were represented; it endeavoured to fix international standards for biological assay. So far nothing has been done in the *British Pharmacopoeia* in this direction to protect the medical public.

### THE NERVOUS CHILD.

THE discussion at the Annual Meeting of the British Medical Association at Portsmouth (BRITISH MEDICAL JOURNAL, November 24th, p. 963) and that on the same subject at the meeting of the Medical Officers of Schools Association reported this week (p. 1098) mark the extent of the change which has occurred of late years in the attitude of adults in general and of the medical profession in particular towards children. In the eighteenth century, in the Spartan Wesley family, the children, even babes, were not allowed to cry, and they did not. In those days and for long afterwards

## THE "LANCET" CENTENARY DINNER.

in celebration of the centenary of the Lancet a dinner was given to the proprietors and staff of that journal on November 29th. A company of more than four hundred gathered at the Hotel Victoria, Northumberland Avenue, with Sir Donald MacAlister, K.C.B., in the chair. Among those present as sponsors for the dinner or their guests were:

S.E.M. de Combe de Saint-Aulaire (French Ambassador), Lord Hewart (Lord Chief Justice), Sir Egon Sprague (Editor of the *Lancet*), with Lady Sprague, Viscount Bunsford, Sir Louis Newton (Lord Mayor of London), Sir Humphry Rolleston (President, Royal College of Physicians of London), Sir John Bland-Sutton (President, Royal College of Surgeons), Vice-Admiral J. Chambers (Medical Director of General Navy), Lieut-General Sir William Leishman (Director of General Staff), Major-General J. B. Smith (President, Indian Medical Service), Sir Commander D. Munro (Director of Medical Services, Royal Air Force), Sir George Newman (Chief Medical Officer, Ministry of Health and Board of Education), Sir Charles Sherrington (President, Royal Society), Sir W. Hale-White (President, Royal Society of Medicine), Lady Barrett (President, London Association of Medical Women), Mr. H. J. Waring (Vice-Chancellor, University of London), Sir Walter Fletcher (Secretary, Medical Research Council), and Sir Stanley Leitch (First Civil Service Commissioner).

The British Medical Association was represented by Mr. C. P. Child (President), Dr. R. A. Dohm (Chairman of Council), and Dr. Alfred Cox (Medical Secretary), and the doctors by Sir Dawson Williams (Editor) and Dr. N. G. Horner (Assistant Editor).

In proposing the loyal toast, Sir Donald MacAlister remarked that His Majesty had been pleased to accept the Diploma conferring upon him the Honorary Fellowship of the Royal College of Surgeons, but with equal graciousness he had been persuaded not to present that Diploma to the General Medical Council for registration, thereby most considerably relieving that body and its President from a situation that would have been embarrassing.

## THE PROFESSOR OF MEDICINE.

The Right Hon. Lord Hewart (Lord Chief Justice) proposed the toast of "The Profession of Medicine." He began

with a few remarks in jocund vein on the association of medicine and the law. The two professions received unstinted and universal gratitude. With the single exception of the law, there was no profession more devoted to the art of healing than the medical profession; again, with the exception of the law, there was no profession which was either that by reason of intimacy due to disease of the mind he did not know what he was doing was wrong, or that he did not know that what he was doing was wrong, or that he put forward in the answers of the judges to the questions asked them in the *Alphington* case (1843). But he understood that a third alternative was now recommended—namely, that a person might still be held not to be responsible, although he knew what he was doing, and that that was doing was wrong, it, nevertheless, by reason of disease of mind, he was uncontrollably impelled to do it. It was indeed to be the law, he would not say that they were launching upon a sea which had no shore, but certainly they were launching upon a sea the shores of which were far more widely separated than the shores between which as lawyers they had hitherto navigated.

The President called upon "Sir Humphry Rolleston, my former pupil, and Sir John Bland-Sutton, my former master," to respond to the toast.

Sir Humphry Rolleston reviewed the changes that had taken place during the last century in medicine. Whatever the present condition of the body politic, those who spoke for medicine would be tempted to adopt the attitude of Dr. Pangloss that in this department of human affairs the present had seen the rise and the results of laboratory research years had seen the best of all possible eras. The last hundred

in medicine. It was nearly a hundred years ago that the idea of the modern laboratory originated; he inscribed Burkin's physiological laboratory in Breslau and Liebig's chemical laboratory in Giessen. The leading position of British physiology and neurology must be regarded as the outcome of this method of investigation. The middle third of the nineteenth century was pre-eminently that of structural pathology, while the remaining part of the century saw the rise of etiology after the founding of bacteriology by Pasteur and Koch. Later the practical application of this new science to surgery was followed by Albrecht Wright, whose dictum, "The physician of the future will be an immunizationist," represented an ideal not yet finally reached. With the inspiration of etiology, preventive medicine, especially in tropical diseases, had led to an enormous saving of human life. The present century was the era of research into functional disorders of biochemistry, chemotherapy, and comparative medicine and pathology. He went on to speak of the increasing share which the Government was taking in the prevention and control of disease, also to the increase of team work both in research and clinical practice. What the future might bring forth in the way of State service and State-run hospitals remained to be seen, and though this consummation did not appear to be devoutly wished for ("Hear, hear") it should be considered with an open mind. The early stages of disease still remained a problem for extensive investigation, and perhaps after all, while they were congratulating themselves that they did not live in the reign of the fourth George, they were still only looking out from the borders of the promised land of health.

Sir John Bland-Sutton, while hesitating to talk about surgery, said that he would trespass a little on the province of the physician. In all religions of the world there existed the belief that from time to time gods assumed the form of the physician. In all religions of the world there existed the belief that he would trespass a little on the province of the physician. In all religions of the world there existed the belief that he would trespass a little on the province of the physician.

In our gross bodies there were smaller bodies called ductless glands, and it was the action and interaction of the gods of this glandular pantheon which determined our mortality or moroseness, our wit or wantonness, our fame or infamy, and whether we were fat or thin, dwarf or giant. If it happened that one or other of the gods was idle the balance was disturbed, and clever physicians observed the signs and symptoms, noted the balance by injecting an extract of the corresponding gland from perhaps the chimpanzee, of the armadillo, or the ass. Sir John Bland-Sutton then turned to say a few words about sugar, a remarkable substance, whether regarded from the point of view of commerce or of science. In the production of cane sugar enormous fortunes had been made and lost, and it had been a source of profit to physicians. To surgeons it had been a source of dismay, for unsupersaturated sugar in the urine was as big an obstacle to the surgeon as an uncharted rock to the mariner. When the islands of Langerhans were first discovered they were regarded as histological curiosities, but it was now known that they exercised a greater influence on human fortunes than the comet which was reported last month in the constellation of the Ram. Physicians as a rule planned themselves that although they got their living by attending to the sicknesses and frailties of human beings, they were active in trying to find the cause of disease and destroying the very agent out of which they got some sort of a living. If he were speaking in the House of Commons he would say, "Mr. Speaker, I can assure you that the discovery of insulin has raised the cost of human sugar to the enormous sum which physicians passed upon themselves no longer held good. To wipe out the reproach they must set to work to find some synthetic substance—coal-tar, perhaps—

## Reviews.

### MEDICINE IN THE WAR.

THE second volume<sup>1</sup> of the *Medical History of the War* dealing with *Diseases of the War*<sup>2</sup> contains three sections in particular which must be of prime importance to all students of the art of war as well as to military physicians and surgeons—namely, the sections on war neuroses, the medical aspects of aviation, and the medical problems of gas warfare.

It is not only the medical services which are concerned with neurasthenia and the war neuroses. Medical officers may encounter curious problems in psychology and in the frailty of the nervous "make-up" of man, but to the Adjutant-General these problems threaten incalculable and conceivably avoidable wastage of man-power. Captain W. Johnson's account of neurasthenia and the war neuroses in France is admirable up to a point. His observations suffer, however, from being confined almost entirely to stationary warfare, as seen in the Second and Fifth Armies in the Ypres salient and at the base in France. He describes in detail the arrangements for retaining casualties from psychical disorders in the army (that is, forward) areas. There is scarcely a hint that when military operations changed into a "war of movement" these arrangements were a hindrance without any compensating advantages. The "N.Y.D.N." centres were left miles behind, yet were still under the administration of an army which, in 1918, was rapidly advancing, so that valuable R.A.M.C. personnel (officers, nurses, and other ranks) credited to the strength of the army were hopelessly lost in back areas. The vaunted moral advantages of keeping the patients within earshot of the guns no longer existed; the centre became isolated in some remote spot, wasting personnel, and, almost more important, wasting transport. Even in a stationary army the moral advantage was highly doubtful. This chapter would have been more useful as a guide in future campaigns if the neuroses of war could have been described also from the viewpoint of the regimental M.O. or an A.D.M.S. of a Division like the Guards. Thus it comes about that there is a complete lack of evidence as to the real factors which minimize wastage from psychical factors. Frank criticism from the "front line" standpoint of the fighting value of men sent back as cured would have enriched this chapter. It is said (on p. 44) that the occurrence of relapses amongst patients treated in France was never a very serious problem. The practical lessons of the war are probably best expressed in the report of the War Office Committee appointed in 1920, whose findings are epitomized on page 65. The recommendations of this Committee will meet with the whole-hearted approval of combatant officers and of every medical officer who served with the fighting troops.

Lieut.-Colonel Henry MacCormac's chapter on skin diseases deserves special attention and the highest commendation. Skin diseases as a cause of wastage did not gain the notice they demanded until Colonel Soltau drew up in 1917 his memorandum on the classification of admissions to hospital in the Second Army. Then for the first time in the annals of military hygiene the real importance of skin diseases in the field was made clear. Dr. MacCormac expands this theme in language intelligible to the non-medical mind. The occurrence and spread of various skin affections (and diseases derived therefrom) are described under the headings of scabies, impetigo, pediculosis, and tropical dermatoses. The part played by seborrhoea in the causation of impetiginous eczema is rightly emphasized. The extent to which wastage of men could be avoided by adequate provision of baths and clean clothing ought to make the appointment of "O.C. Laundries" one

of the principal staff billets in all future campaigns. German bathing and delousing stations were the one heritage of their occupation upon which we entered joyfully when we advanced in 1918.

Veneral diseases had a pitiable share in the production of invalidism from all fronts. Lieut.-Colonel Harrison writes temperately on this subject. Such hotly debated questions as prophylaxis and early disinfection he leaves as being too controversial for the evidence brought forward to assist materially in judging of their real merits. One paragraph in his article mentions the almost unaccountable difference between the British rates of venereal infection and those of the Dominion forces. He says: "The average British soldier proceeded to some village or small country town; the average soldier of the Dominion forces found his way to London. The former found abundant distraction in many home interests, the latter had perforce to seek more artificial amusements. The first operated against sexual incontinence, the latter favoured it." By comparison with this all other measures of prophylaxis sink into insignificance. The organization of special treatment centres is well described, but the results of treatment were not on the whole encouraging.

The medical aspects of aviation and examination of candidates (by Lieut.-Colonel Bowdler) bear witness to the scientific spirit which animates the youngest branch of our fighting forces. In the navy and army the interference of the physician and physiologist are not so gladly suffered. The Air Force allows scientific medicine almost a free hand in appraising the fighting qualifications of officers or flying ranks. This attitude was the outcome of the institution of a special medical board at the end of 1916 for the purpose of examining candidates and dealing with officers and pupils who had broken down. The results of the experiment were soon evident; at the end of a few months the percentage of pupils breaking down during training was reduced by 50 per cent. The methods used for testing candidates' fitness and their temperamental aptitude for flying are extremely interesting. In popular parlance, "guts" were the essential qualification, and the medical officers of the Air Force devised many subtle ways of discovering those candidates who had "guts" and those without any. These tests did not require elaborate scientific apparatus, as witness the so-called "breath-holding or respiratory test." Wing Commander Martin Flack considers that British experience proved that a history of special aptitude at various sports requiring eye and hand co-ordination as well as physical stamina is of equal value with experiments based on psychomotor responses to stimuli in assessing mental fitness for flying. The value of oxygen administration in aviation was left unsettled when the war ended. Martin Flack says: "The dislike of wearing something over the face when fighting for one's life is not prejudice but instinct, and constitutes one of the problems which the future has to solve." Even the men who climbed highest on Mount Everest are not agreed on the solution to the same problem.

Nearly half the volume is given up to the story of gas warfare. The employment of poison gases in warfare filled the civilized world with horror, yet it seems from these chapters that the rates of mortality and of permanent invalidism that gas can cause are far below the corresponding rates resulting from any other weapon of modern warfare. In other words, the man who becomes a "gas casualty" has a better prospect of escaping with his life and of recovering completely from his disablement than the man hit by shell, bomb, or bullet. This was not the conception of the man in the trenches nor yet of the public at home. Unpublished figures showed that in one army in 1918 during heavy gas attacks 60 per cent. of all gas casualties were fit to return to the line in a fortnight. The most fatal gas was chlorine, but the difficulties of directing it with certainty against the enemy limit its employment. A change of wind brings the chlorine cloud back into the faces of the troops launching the gas. Phosgene, too, is difficult of directional control, whilst both gases are efficiently guarded against by masks, and disperse rapidly. Mustard gas delivered in shells proved by far the most potent weapon of attack. It could be placed where it was

<sup>1</sup> The first volume of this part of the series of volumes edited by Sir W. G. Macpherson was reviewed in our issue of October 14th, 1922, p. 691. The two volumes which treat of surgery were reviewed in our issues of February 17th (p. 253) and February 24th (p. 332), 1923.

<sup>2</sup> *The Medical History of the War, based on Official Documents: Diseases of the War.* Vol. II. By Major-General Sir W. G. Macpherson, K.C.M.G., C.B., LL.D., Major-General Sir W. P. Herringham, K.C.M.G., C.B., Colonel T. R. Elliott, C.B.E., D.S.O., and Lieut.-Colonel A. Balfour, C.B., C.M.G. London: His Majesty's Stationery Office, 1923. which would furnish a drug as easily obtainable and purchasable as aspirin and which could be used for the advantage of diabetics. Care must be taken that this drug did not get into the hands of a druggist who would corner it, for such a druggist, having amassed a great fortune, might turn philanthropist in later life and devote his millions to the rebuilding of the Royal College of Physicians and to reimbursing physicians themselves for the heroic losses, bravely borne in the true spirit of the profession, which they had sustained through the absence of diabetics from their consulting rooms. (Laughter.)

#### THE "LANCET" AND ITS FOUNDER.

Sir BERKELEY MOYNIHAN, in proposing the health of the *Lancet*, paid that journal many compliments, but reminded the company that it had not always been as gentlemanly and persuasive as in these latter days. A hundred years ago, when the *Lancet* was founded, the profession was the victim of many abuses, from within and from without its own ranks. The Apothecaries Act was then only eight years old, and there had been no time, inclination, or opportunity for the organization of the profession. The profession in those days suffered from vexatious and intolerable things, from shameless nepotism, from harsh and unjust ordinances of governing bodies, from despotic methods among teachers and examiners which rankled in the minds of the general body of practitioners, but for which there was no redress. The *Lancet* helped to change the picture. It was born in an age when men were restive against authority. The French Revolution and the revolt of the United States had affected the mind of a generation. Thomas Wakley lost no opportunity of attacking privilege and injustice. Looking back upon that stormy figure, they had to acknowledge that his contentions were almost always right. His methods of procedure were perhaps crudely conceived, and carried out with something approaching savage rancour, but he was fighting against interests which were disregarding of the rights of others, and possibly no other procedure would have gained his end. He bestowed now and then a word of praise, but in general his onslaught was as virulent as it was persistent. Wakley's achievements called for admiring gratitude. His robust independence, his faith in great causes, his loathing of injustice, his disdain for that professional eminence which was built only upon favour, appealed to them all. His pungent wit, his merciless invective also attracted them, because, although these powers were harshly used, they were never, he thought, used unfairly. Men such as Wakley were brought into being in all countries of the world, but especially in our own, where the human spirit was quickly roused to active protest when strength was devoid of right, or control was dictated by caprice. Monuments to the benefactors of the past were sometimes carved in stone or cast in bronze, but few memorials were so enduring as the journal which perpetuated the memory and labours of Wakley. From Wakley's day to this the *Lancet* had grown in influence and authority. Its pages steadily reported the progress of medicine, and by its help greater medicine had been inaugurated. The world was a little weary of journals, especially those which, unmindful of responsibility, sought ever for larger circulations and greater power. The first duty of journalism was to educate, to enlarge the general outlook, to stimulate men to a sense of responsibility, and to convey truth. In this task vigour was necessary, and humour would not come amiss. But honesty in the search, and truth as the distant goal, and sanity in expression were the attributes of the highest journalism, and these the *Lancet* had always shown, and never more plainly than under the guidance of its present editor. (Applause.)

Viscount BERNHAM, on behalf of the newspaper press, joined in the tribute. It was said that those who made idols were never idolaters, and he was free to confess that he did not idolize his journalistic contemporaries. But he did admire that great section of journalism which was devoted to technical and professional interests. While the circulation of the daily newspapers was national, the circulation of the professional and technical press was world-wide. Wakley's achievements greatly interested him, but as a journalist the thing he admired most about Thomas

Wakley was that, whereas ten libel suits were brought against him, in which a total of £8,000 was claimed as damages, all he had to pay was the sum of £150 and one farthing!

Sir SQUIRE SPRIGGE, who was received with prolonged applause, said that although the foregoing speeches provoked reminiscence, he declined the invitation to indulge in memories. The past outrageous energies could never be repeated. The violence of past days was gone, but the desire for the right and the zeal to achieve it remained as forcible as they were a hundred years ago. He likened the centenary dinner to a milestone on the road of progress, and himself to a robin sitting twittering thereon. The *Lancet* was a friend-made paper. It relied on the good offices of its supporters who read each other's wisdom and clarified and corrected each other's views. If he might be forgiven a personal note on that occasion, he himself was a friend-made man, and he had called shamelessly upon the services of his friends. Through school, college, and hospital associations he had exacted levies from them, and as time went on enlarging environment gave him enlarging opportunities for such exactions. Further, any measure of success which he had gained had been in return for labours which he had loved to pursue. It was those who had to discharge a dull routine and to face distasteful duties whose devotion was really admirable, but as for himself he had enjoyed his work; it had been his delightful duty to record the phases and ramifications of medicine, which, although it might be only one section of the world's activities, was ever-developing and all-permeating. (Applause.)

Sir ERNEST HODDER-WILLIAMS, Chairman of the Directors of the *Lancet*, also responded to the toast, and expressed his great pleasure that when the change of proprietorship took place it involved no change in editorial direction, and that there never had been a single matter of policy upon which the Editor and Directors had not been in spontaneous and complete accord.

#### THE GUESTS.

LORD DAWSON OF PENN proposed the health of the guests. If they were right in saying that a man might be judged by his friends, surely that distinguished assemblage gave vivid and delightful expression to the appreciation in which the *Lancet* was held. The company represented other professions than the medical, and the professions had need to understand each other. Medicine in former days held itself in almost monastic detachment from social progress. But now that the health of the community, and not merely the cure of disease in individuals, was within its orbit, and was likely in the future to claim a dominant part of its attention, contact with other callings must be more close, and the thoughts and conclusions of medicine a necessary part of all-round statesmanship. That evening they were honoured by the presence of the French Ambassador, the genius of whose people had created much for which civilization stood, which genius was ever and abundantly evident in the field of medicine. The Lord Chief Justice was also among them, one of those disciples of the law who could not only entertain thought but adequately phrase it. Lord Burnham represented the Press, and the speaker could not help noting the conflict of advice which the Press gave in the nation's present controversies; evidently it was not only doctors who differed! In the Press also there appeared to be a good deal of reliance on "expectant treatment." A guest to whom they gave a special welcome was Mr. T. J. Wakley, now at Oxford, a great-grandson of the founder of the *Lancet*. He coupled with the toast the name of the Lord Mayor, who brought with him the lustre of personal distinction earned in the field of civic administration, and of Sir Dawson Williams, who had found in journalism the greatness of medicine, and in medicine the greatness of journalism, and to the great advantage of them all upheld the best in both. (Applause.)

The LORD MAYOR briefly expressed his pleasure at being present, not only as a civic administrator, but as President of the Hospital Sunday Fund, and spoke of the close connexion between the Corporation of the ancient City and the profession of medicine and organization of charity.

Sir DAWSON WILLIAMS offered to the *Lancet* the congratulations of what he supposed was the smallest specialty

CLOTHES MOTHS.

PROFESSOR LEVADITSKY'S Habdon Lecture, announced in our last issue (p. 1071), will be delivered in English on December 11th, 12th, and 13th, at 5 p.m., at 37, Russell Square, W.C.1. All interested are invited to attend.

The late Dr. Margaret Lucy Augusta Bollean of Wycombe, who left net personality of £16,183, has bequeathed £200 to the Norfolk and Norwich Staff of Nurses, Ltd., and £100 each to the Norfolk and Norwich Hospital, the Royal Free Hospital, Gray's Inn Road, and the Elizabeth Garrett Anderson Hospital, Euston Road.

DR. KONSTANTIN VON MONAKOW, professor of neurology in the University of Zurich and the author of numerous works on the normal and morbid anatomy of the brain and spinal cord, has recently celebrated his seventieth birthday.

A MONUMENT to the late Professor Monroville, the well known surgeon of Angiers, was recently unveiled there by Professor Hartmann of Paris.

As, owing to printing difficulties, the Journal must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the British Medical Journal alone unless the contrary be stated.

LETTERS TO THE EDITOR.—It is particularly requested that all communications on the editorial business of the Journal be addressed to the Editor at the Office of the Journal.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not

Authors desiring reprints of their articles published in the British Medical Journal are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

The postal address of the British Medical Association and British Medical Journal is 429, Strand, London, W.C.2. The telegraphic

**DANGEROUS DRUGS ACT.**

"SENEX" asks if his local pharmacist is right in refusing to supply him with opium for domestic use on the ground that he is relied from active practice. "I was under the impression," he adds, "that the final revision of the Regulations under the Act withdrew this very provision largely through the efforts of the BRITISH MEDICAL JOURNAL."

“The pharmacist is wrong. He cannot refuse to supply opium to a registered medical practitioner” on the ground that he is refused from active practice.” The amending bill to the Dangerous Drugs Act, 1920, sought to impose a restriction on the sale of dangerous drugs to registered medical practitioners “not in actual practice,” but on strong representations by the British Medical Association and Journal the words “in actual practice” were removed from the bill by an amendment moved by the Home Secretary. The pharmaceutical should be referred by our correspondence to Clause 3 of the Dangerous Drugs and Poisons (Amendment) Act, 1923.

INCOME TAX.

... now sold the latter for £70, buying a 16-hp. "B" car for £500. The fact that he had an allowance for the "O" car does not affect the allowance due on his second renewal. The case referred to by "W. G." was complicated by the fact that the sale of the old car and the purchase of a new one were

SIR ROBERT ARISTOTLE-JONES writes: "A CORRECTION.

DR. GRAYMAN GRANT wishes to thank the many correspondents who have written to him about ideal and unidealities.

---

*'The Simpler Investors' Pocket Diary*, now in its tenth year of issue, is published by the proprietors of the *Financial Review of America* in conjunction with Messrs. Charles Feltz and Company. The 1924 editio includes special features which should prove useful to investors for reference. The diary has a back loop and pencil and is fitted with a self opening memo tablet and leather pockets for stamps, cards, etc. The sale price is 3s. 6d.

**VACANCIES.**

NOTIFICATIONS for offices vacant in universities, medical colleges, and for various other appointments in hospitals, - will appear from time to time in the following columns:-

Advertisements are received at a charge of 6d. per line, and published free of cost if they contain a summary of vacancies or notices in the advertisement and do not exceed 25 and 55.

in the medical profession—namely, medical journalism. Very few journals lived to celebrate their centenary. Times changed, and it required great powers of adaptation and phylactic vigour for a journal to adjust itself to the changing environment. The phylum of editors of the *Lancet* had shown this vigour from its founder and first editor down to his friend, the present editor, Sir Squire Sprigge, in whose hands its natural force had been in no way abated. A medical journal could not exist in these days unless it had the support of the profession. In saying this, it was not of the subscription list he was thinking, but of the support which came to such journals from specialists on every side, who were ready to place their knowledge at the journal's disposal. The principal motive which actuated them was probably love for their own particular subject, though they were moved also by a desire to help their colleagues, and perhaps by a feeling of loyalty to a certain journal. A general medical journal must at least touch on the immense variety of subjects raised by the progress of science in every department, and every author seemed to feel the necessity of writing at greater length than before. (Laughter.) This tendency affected all the sciences, and even the pure mathematician would replace a column of type by a formula so long that it must be printed lengthwise on the page! The multiplication of special journals was to be commended. Their conductors had their reward in the knowledge that they were smoothing the road for their fellow workers. He likened such journals to the large-scale ordnance maps which a man obtained when he wanted to buy an estate, but the general medical journal was like the map for the whole kingdom—the inch to a mile. He associated himself with all that had been said about the *Lancet*, and offered his good wishes for its future. (Applause.)

Sir CHARLES SHERRINGTON proposed the health of the Chairman, a toast which was pledged with much heartiness. Sir DONALD MACALISTER thanked the company for their kind forbearance with a chairman whose state of health was not of the best, and who was doubtful almost to the last whether he would be able to come at all. He joined in the tribute to Sir Squire Sprigge, who, to paraphrase the lady's description of her husband, was "more like a friend than an editor."

## Paris.

[FROM OUR CORRESPONDENT.]

VERY comforting is it in these troublous times to discover that frontiers are not heaven high. The petition recently signed by the Academy of Medicine pleading for the maintenance of the Lister ward in the Glasgow Royal Infirmary is very significant in this respect. Few of our Academicians can ever have seen the ward, but there is not one who does not claim with pride to be the fellow citizen of Lister in the ideal city of science and humanity; there is not one who does not wish reverently to preserve for ever the footprint of Lister on the shifting sand of the ascent of man. We know next to nothing about the main question of the present necessities of the Glasgow Infirmary; we only ask ourselves, "What would Lister desire?"

The Spahlinger problem confronts us also in an unfortunate form owing to the publicity it has received in the public press; the public are told on the one hand that tuberculosis is conquered at last by a secret remedy, and on the other hand that this remedy is not available. Rarely has there been a more bitter jest. The general attitude of the medical profession betrays its indecision: for the first time we are asked to make an act of faith in the scientific sphere, and to turn our back on every principle that has been taught since Descartes. Faced with a problem the solution of which all the world is feverishly awaiting, we are asked to accept uncontrolled assertions. Three years ago when Spahlinger visited the Pasteur Institute, Dr. Calmette suggested to the Genevise researcher that he should proceed to publish the proofs which are indispensable, yet the secret was still kept. Unlike Great Britain we believe in Spahlinger, but we feel somehow that we

are being false to a treasured tradition; the spirit that was in Pasteur, Lister, and Koch must not leave us.

The annual meeting of A.D.R. has revealed the fine progress made by this Association for the Development of Medical Relations between France and the countries belonging to the League of Nations. Our Foreign Office has instituted a department which is working in association with the Faculty of Medicine. A medical society has been started in conjunction with the Argentine Republic which is erecting a building for Argentine students in the students' quarter on the site of the dismantled fortifications. We hope that others will follow this example and that in the end we shall succeed in establishing an organization for post-graduate study. Professor Hartmann is energetically arranging courses of instruction so that foreign students may be able to concentrate their work into the minimum of time, following the example of Vienna before the war. It is hoped that a similar organization will be formed in every country, and that the time will come again when no man of science will begin to practise without having previously studied in a foreign school. So once Sir William Osler dreamed.

In the large amphitheatre at the Sorbonne there has just been held an important meeting to discuss international co-operation. M. Romain Coolus, the president of the *Confédération des Travailleurs Intellectuels*, set out the objective of this movement with which the *BRITISH MEDICAL JOURNAL* has already concerned itself. M. Destrée, at one time Minister of Art and Science in Belgium, spoke on the subject of co-operation of the League of Nations in intellectual matters. So from all sides comes the watchwords Co-operation and Mutual Understanding. Everyone should set himself to bring his stone to be built into the rampart which is menaced by the wave of gross materialism flung against it by the world crisis: particularly clear is the duty of the doctor whose culture is essentially world-wide.

The death of Dr. George Linossier, of Vichy, has robbed France of one of her best workers. He took up medicine late, having given himself first to chemistry. This foundation, was however, of great assistance to him. He devoted himself to the study of metabolism, a subject on which he became an expert authority. His solid scientific attainments enabled him to tackle the problems of gout and diabetes with a clarity of vision rarely met with in a clinician. We owe to him many theoretical publications on proteid metabolism and some practical observations produced by his experience in a very large private practice. To Linossier belongs the credit of having explained the significance of "diarrhée prandiale," and of demonstrating the value of a reduced diet in the treatment of diabetes, twenty years before it received the unanimous recognition now accorded to it. His nature was simple and modest. He was a professor agrégé at Lyons and a corresponding member of the Academy of Medicine. He leaves to his colleagues the finest example of the virtue which characterized him all his life—uprightness.

## England and Wales.

SUN AND AIR.

At a meeting of the Royal Society of Arts on November 28th Sir Henry Gauvain repeated the now familiar story of the work in the Treloar Homes at Alton and on Hayling Island among children suffering from surgical tuberculosis. His photographs illustrated even more effectively than his words the excellent results secured. Lord Dawson of Penn, who presided, said that if he allowed himself to indulge in prophecy he would declare that in the region both of diagnosis and of treatment there was no direction in which the power of knowledge over health and disease would be more prolific of results during the next few years than in the scientific utilization of the action of radiations and the action of air. Dr. Rollier of Leysin must be regarded as a pioneer in the scientific application of that which had been known and applied in a loose

empirical way for ages. In this country, thanks to the late Sir William Treloar and to Sir Henry Gauvain, a successful scheme had been organized along the same lines, in spite of the fitfulness of our sun and the gloom of our winters. It appeared that the ultra-violet constituents in light raised the resisting and fighting power of the blood against infection, and thus a possible field for the treatment of many diseases at present baffling was opened up. Caution, of course, was necessary, because any application of such treatment beyond what careful research had indicated was likely to do harm and not good. He thought that Sir Henry Gauvain's results would have an effect on the general hospital service of the country. There would be a tendency for hospitals to be removed from cities, and for only such accommodation to be retained within the cities as was necessary for the reception of cases or for dealing with cases whose stay in hospital was likely to be brief. In the ensuing discussion, Mr. A. Green, a master in charge of the open-air schools of the London County Council, spoke of the successful institution of a sun-cure class at Stowey House, the L.C.C. school on Clapham Common, for "pre-tuberculous" children. This class was held last summer, and although the climatic conditions were far from satisfactory the thirty-six youths from the slum areas of South London who constituted the class showed distinct improvement both in physical and mental capacity. Next year, given a better summer, it is hoped to extend the experiment. Dr. Harriette Chick recalled her experiences in Vienna, where infants suffering from rickets had shown no particular improvement so long as they were kept in the ward, however well lighted and well aired, but in the cold sunshiny spring to which Vienna was accustomed these infants were placed out on the verandah, and within a very short time the improvement, as shown by the x-ray photographs periodically taken, of the bone formation was quite definite.

## Scotland.

### ROYAL EDINBURGH HOSPITAL FOR INCURABLES.

At the annual meeting of the Royal Edinburgh Hospital for Incurables (Longmore Hospital), held on November 30th, Sir Henry Cook, Chairman of the Board of Management, who presided, announced that an anonymous donor had presented £10,000 for the purpose of improving the accommodation for the nurses. Plans had been prepared for a greatly improved dining-room, for a recreation room, lecture room, and for sick-room accommodation. The work was already in hand and the chairman hoped that this valuable addition to the hospital would be ready in another year. In the report submitted by the surgeon and physician to the hospital, Sir David Wallace, P.R.C.S., and Dr. Robert A. Fleming, F.R.C.P., it was mentioned that a number of cases had been discharged cured during the past year. A former patient who suffered from tuberculous disease of the spine, and who had been under treatment for about three years, was now successfully pursuing his profession.

### CENTENARY CELEBRATIONS OF THE ROYAL (DICK) VETERINARY COLLEGE, EDINBURGH.

During the last week of November a series of meetings and social functions were held to celebrate the centenary of the foundation of the Royal (Dick) Veterinary College at Edinburgh, by William Dick in 1823. Professor M'Eachran, LL.D., F.R.C.V.S. of Quebec, Canada, has presented a portrait of William Dick to the College. On November 27th Professor Theobald Smith, director of the department of animal pathology in the Rockefeller Institute for Medical Research, at Princeton, New Jersey, delivered an address in the University on "Comparative Pathology." After discussing some of the more technical aspects of animal pathology, he referred to its economic significance. Many of the causes or accessory factors of disease among animals were made by man. The task of the pathologist was to find methods to counteract the evil consequences arising from man's exploitation of animal

life. The solution must differ from that demanded in human medicine. In the latter it was anything to save life, but in animals individual treatment must in a way be replaced by more preventive measures.

On November 28th the celebrations were continued by an oration from Sir John MacFadyen, LL.D., who said that in a sense the science connected with disease among the domesticated animals was quite modern. The first veterinary college had been founded at Lyons in the middle of the eighteenth century. In 1791 a school was founded in London, and William Dick had become a pupil of this school in 1817. Five years later he founded the College in Edinburgh. Speaking of foot-and-mouth disease, the lecturer said that in the present state of knowledge the veterinary profession could not be held guilty of incapacity because the virus of the disease in some obscure and indirect method at intervals found its way into this country from abroad. Stock owners in Scotland might, at least, be thankful that they had not been farming on the Continent of Europe during the last four years; they owed their comparative immunity from the disease in the last thirty years to the vigilance of the profession. With regard to glanders, the losses in the British Army from 1914 to 1918 were almost negligible in comparison with those experienced in recent great wars, and smaller than in the armies of any of the other combatants. In nearly every other civilized country the progress of veterinary science had been viewed as a concern of the State, and in France and Germany the maintenance grants to veterinary schools for a single year before the war exceeded the total amount given by successive governments of this country for veterinary education during the last 120 years. The greatest progress in the knowledge of animal diseases had been made in the last fifty years, during which period veterinary pathology had commenced to stand on its own legs. It would not be possible to create a class of men with an intimate knowledge of both human and veterinary pathology, but it would be better if veterinary surgeons knew more about human pathology and doctors more about animal diseases. The future progress of veterinary science in this country would largely depend upon whether it was at last considered worthy of national support, but next to that it would depend on the number of those who would enter the profession fully determined to leave it better than they had found it. Lord Forteviot presided at a reunion dinner held in the Royal College of Surgeons, which was attended by over 100 guests and members of the Veterinary College. Lord Provost Sleigh, in proposing the toast of the Royal (Dick) Veterinary College, traced its development from the time in 1823 when William Dick was appointed lecturer by the Highland Society of Edinburgh, later the Highland and Agricultural Society of Scotland. In 1844 the Royal College of Veterinary Surgeons came into existence by Royal Charter, and in 1916 the classes had all been transferred to the present building, where it was destined, he hoped, to a new era of prosperity.

With the object of raising a sum of £10,000 to institute a post-graduate Fellowship for animal research, a three-days' bazaar was held in the Music Hall, Edinburgh. The opening ceremony was performed by Field-Marshal Earl Haig, who said that they were taking part in a function of much more than local importance, and the occasion gave him an opportunity to say a word of thanks to a profession which, during the war, rendered very notable service to the army he then commanded. As the army grew so did the veterinary corps, and so did the work it had to do. The original Expeditionary Force started with well under 1,000 officers and men of all grades, and 6 veterinary hospitals with accommodation for 1,500 animals. The corps ended the war with 765 officers and between 16,000 and 17,000 other ranks; and 20 hospitals provided accommodation for 40,000 horses. The Expeditionary Force started with 53,000 horses, and in the course of the war this total reached a maximum of 475,000. This did not, however, represent anything like the whole work of the veterinary profession, for disease was reduced to a minimum. The skin disease statistics had been the envy of our allies; glanders, that scourge of the armies of other wars, was banished altogether; and while foot-and-mouth disease was raging throughout the

territory in Belgium occupied by our allies, they asked for help from our veterinary officers, who gradually stamped it out, and—what was more important—prevented the disease from coming to Great Britain.

## Ireland.

### DUBLIN BOARD OF GUARDIANS DISSOLVED BY MINISTRY OF LOCAL GOVERNMENT.

The following letter has been addressed by the Ministry of Local Government to the clerk of the Dublin Board of Guardians:

I am directed by the Minister for Local Government to state that he has had under consideration the report of Mr. Seumas McElysaght, Inspector, on his recent public inquiry at the Dublin Union. A copy of the report is forwarded herewith. The Minister is satisfied from the facts adduced in the report that the duties of the guardians in the Dublin Union are not being duly and effectually discharged. He has been impressed by the inspector's comment—that the work of an elected board of seventy-two members has been in effect mainly carried out by only twenty-five, and that there was reason to believe that the sporadic attendance of negligent members had nullified the efforts of those who had been devoted to their public duties. It appears obvious to the Minister that it has become an imperative duty on him in the interests of effective and economical administration to dissolve the guardians of the Dublin Union. The decision is embodied in the accompanying order dissolving the Board of Guardians and appointing Mr. Seumas Murphy as the person to whom their several powers and duties have been transferred. The Minister trusts that those who have been guardians and others interested in the important public functions with which Mr. Murphy has been entrusted will accord to him a full measure of co-operation and assistance.

The Inspector in his report discussed some matters of medical interest.

Referring to the administration under the Medical Charities Act, the report stated that the dispensaries were in a dirty condition. It had been complained that the supply of coats usually received early in October had not yet been delivered, resulting in patients having to wait in the cold. In one instance, mentioned in the report, the Local Government Inspector had failed to find either doctor or porter on the premises during dispensary hours. In all cases the inspector found measure glasses in a dirty state. Medicine seemed to be thrown about in an untidy manner in many cases poison presses were not locked. The report further declared that neglect shown in the past of Poor Law dealing with the boarded-out child, the child at nurse under the Children's Act, and the child adopted on payment of a lump sum, just prior to the present administration, was painful. Evidence showed that an actual system of child farming had been indulged in. The case where six babies died in two years painfully illustrated this. The unregistered nursing home was an equally grave danger. There would appear to be serious need of legislation under which nursing homes, private or otherwise, would be compelled to register before accepting the care of any child.

Supervision of workers by the system is, the report continued, very defective. Serious attention is drawn to the method of making appointments. Attention is drawn to the fact that the collective number of days lost in respect of sickness totalled 23,981, and the total cost of providing substitutes amounted to £7,305. Appointments are made with enthusiasm by the Board, but, it is complained, there is, if anything, a disinclination to order dismissals or suspensions. It would appear (the report continued) that every officer was a law unto himself, and, although the master, matron, and doctors were responsible for the efficient discharge of multifarious duties, the Minister was satisfied that they were not able to exercise that control so very essential to the proper and economical management of various departments. The result of the guardians' indifference in dealing with complaints weakened the authority of the executive, and that served to strengthen dangerous tendencies and cause a spirit of insubordination to develop that would be highly prejudicial to the best interests of the institution. The doctors were powerless to enforce discipline, and complaints received such scant attention that it was only in very exceptional circumstances that the Board was troubled in this respect. The guardians had not exercised proper management in connexion with hospitals, dispensaries, outdoor relief (particularly in rural areas), stores, staffs, appointments, discipline, admissions, and discharges.

A LOCAL centre for combating cancer has been established for the region of Lyons and South-east of France, under the directorship of Dr. Léon Bérard, professor at the Lyons Faculty of Medicine.

DR. G. DE CLERAMBAULT, the successor of the late Ernest Dupré, has recently commenced a course of lectures on urgent psychiatry and psychiatry in general at the Police Infirmary, Quai de l'Horloge, Paris. The lectures, which are free to medical practitioners, are held every Saturday afternoon at 3 p.m.

## Correspondence.

### GAS LEAKS AND CARBON MONOXIDE POISONING.

SIR,—Mr. A. Webster and I have been testing the smellable limit of coal gas and find it about one part in 2,000 parts of air. Gas can just be distinctly smelt when one sniffs the air issuing from a cylinder containing this dilution. Taking the normal percentage of oxygen in the arterial blood as 18, the prolonged breathing of one part of coal gas in 2,000 parts of air would, if there were 10 per cent. of carbon monoxide in the gas, finally saturate the haemoglobin with carbon monoxide to the extent of 1 volume per cent.; if there were 20 per cent. in the gas to the extent of 2.7 volumes per cent. The former is the amount of saturation which Mr. H. Hartridge found in the blood of one heavy smoker. All smokers must have some amount of carbon monoxide in their blood when smoking, and give it off between whiles. Carbon monoxide can only accumulate in the blood up to the saturation corresponding to its partial pressure in the air—no further.

Dr. Hazleton in his paper "On carbon monoxide—a predisposing cause of pulmonary tuberculosis" (*BRITISH MEDICAL JOURNAL*, October 27th, 1923) leads the reader to think that the longer the breathing of air containing 0.01 per cent. of carbon monoxide the greater must be the saturation. This is not the case. Equilibrium is reached and the saturation proceeds no further. There will finally be 2.7 volumes per cent. of carbon monoxide and 15.3 volumes per cent. of oxygen in the blood. The saturation process is a slow one at such a low dilution, but will not go above this figure however long the air is breathed. In fresh air it again escapes from the blood. In the *Journal of Physiology*, vol. 44, p. 275, 1912, "The laws of combination of haemoglobin with carbon monoxide and oxygen" are given by C. G. Douglas, J. S. Haldane, and J. B. S. Haldane.

Suppose the 18 volumes per cent. of oxygen in the blood is diminished by 2.7, this is of no consequence to the resting person because he has more oxygen in his blood than he requires; a surplus is kept ready for use on exertion. Douglas and Haldane found that when the partial pressure of oxygen corresponded to an altitude of 15,000 feet, a 23 per cent. saturation of the blood with carbon monoxide was tolerated without inconvenience (*Journal of Physiology*, 1912, 44, p. 332). Apart from deprivation of oxygen, carbon monoxide has no poisonous effect. There is no evidence that the employees of gasworks, who are daily exposed to the smell of gas, are less healthy than others. Many live to old age and draw their pensions for many years.

The public, of course, must be taught that the least smell of coal gas is a danger signal and that all leaks must be stopped. Only a wanton disregard of the warning smell, the close shutting of rooms, and prolonged breathing can raise the percentage of carbon monoxide in the blood to the danger point.

I gave evidence to the recent Board of Trade Committee, appointed to consider this subject, in favour of allowing a higher percentage of carbon monoxide in coal gas, on the grounds that the cheaper gas becomes and the more it is used for heating the less fouled will be the cities from smoke. Smoke does incomparably more harm to health and happiness than is caused by the few accidental and suicidal deaths resulting from inhalation of coal gas. The Committee, in their report, took this point of view. I hope Dr. Laird will consider it. An essential part of this policy is the teaching of "safety first" in the matter of leaks and fittings.—I am, etc.,

Loughlin, Dec. 3rd.

LEONARD HILL.

SIR,—The symptom-complex described by Dr. Hazleton in the *BRITISH MEDICAL JOURNAL* of October 27th (p. 763) as due to carbon monoxide poisoning is common. The usual train is (1) headache, (2) lassitude and anorexia, (3) shortness of breath on slight exertion, (4) anaemia of the yellow type, not ordinary house pallor. The next stage is myocardial degeneration, evidenced by increased pulse rate, possibly a pushed-out apex beat and signs of

slight dilatation, and evidence of decreased cardiac reserve.

A cultivation of the senses of smell and taste is essential to success in general practice. Diagnosis begins on the doorstep. As I cross the threshold I deliberately savour the smells by drawing a long breath through the nose, and employing also the sense of taste by deliberately "tasting the air." Some aromas merely smell, others only taste, many do both. Small gas leaks only smell; the products of the imperfect combustion of gas—equally if not more dangerous—both smell and taste. Wherever gas is really sensed a lowered condition of health will be found in the whole household, or at least that part of it—mainly, of course, the feminine element—which spends most of the twenty-four hours at home. This occurs very nearly as frequently in the larger houses of the well-to-do as in the small homes of the working classes, but the evil effects in the latter are more pronounced, as these homes are difficult or impossible to ventilate without draughts. In my mind the effects of gas leaks and oral sepsis run a very close race for pre-eminence as primary causes of general malaise, and later of serious disease. I am an enthusiastic gas user; my house is entirely heated by gas fires, and all cooking is by gas. But every fitting fits, and every fire is properly flued, and every flexible tube is renewed every six months and tested very frequently. Dr. Hazleton has indicated one of the sources of gas leaks—namely, the pendent position of the ordinary gas burner cock or tap. But leaks due to this cause form only a tithe of the usual domestic leaks. The gas cooker is by far the worst offender; then comes the gas fire as usually fitted, and the flexible gas tube is a good third. The gas companies will not fix proper flues to gas fires and will not adequately block off the chimney openings up which the gas flue must pass. Consequently nearly all gas fires suffer from a down draught containing much carbon monoxide. Gas-fitters will daub white lead on faulty joints and fail to screw up connexions, and will even at a pinch fix a section of faulty pipe. The modern gas fire itself is as nearly perfect as such an apparatus can be. Until the gas companies and the public generally come to recognize the importance of the prevention of even the smallest leaks the mass of ill health due to this cause will continue. As Dr. Hazleton points out, 0.01 per cent. of carbon monoxide will in eight hours saturate the blood to the extent of 17 per cent. Smaller amounts inhaled daily for weeks will cause chronic ill health even amongst the young and vigorous. To the feeble and aged confined to sick-rooms the results are much worse. Monopolies are not good things, and one wants to see the brave fight between gas and electricity continue. But the gas companies must eradicate gas leaks.—I am, etc.,

October 29th.

M.A., M.D., D.P.H.

#### ETIOLOGY OF CANCER OF THE OESOPHAGUS.

SIR,—In your issue of November 24th Dr. G. D. Parker makes eight "suggestions as to facts to be observed" in connexion with the origin and course of carcinomatous tumours in the human subject.

That the use of the expression "facts to be observed" is, to say the least, unfortunate appears to be realized by Dr. Parker himself, for he rather naively adds, "such facts as here stated are put down as individual observations, and no doubt are inaccurate on many points." In other words, he is prepared to find that some of the alleged facts may turn out to be either unproved or unprovable assumptions, if not obvious fictions.

Under the latter category I would put the assertion "(b) In cancer of the oesophagus—the very common association either with the excessive drinking of concentrated forms of alcohol or of excessively hot fluids." Cases of cancer of the oesophagus investigated oesophagoscopically and otherwise by me can be reckoned not merely by the score but run into many hundreds. The number of living individuals of cancer age who indulge excessively in ardent spirits and in very hot fluids, or both, must be relatively large, say at least 160,000 probably, whereas the number of individuals who acquire cancer of the gullet is comparatively small—the average yearly death rate for England and

Wales from gullet cancer for the ten years 1911 to 1920 was a little under 1,600! In my investigations the number of those individuals who were found to be the victims of cancer of the oesophagus who gave a clear history of excessive drinking of either ardent spirits or very hot fluids or both has not been such as to impress me with the correctness of the alleged association implying cause and effect which Dr. Parker formulates. The conclusion I have arrived at is, of course, quite contrary to my preconceived expectations based on what I was taught as well as on *a priori* grounds.

There would not appear to be anything antecedently improbable in the suggestion, in accordance with current teaching, that the consumption of large quantities of unwatered spirits and hot drinks might be one of several possible factors operative in the origination of cancer in the buccal cavity (including the tongue), the fauces, the pharynx, the gullet, and the lesser curvature of the stomach; all that I can affirm is that in my large series of cancers of the gullet I have failed to find any convincing evidence of the frequent presence and operation of this factor as a predisposing or exciting cause.—I am, etc.,

London, W., Dec. 4th.

WILLIAM HILL.

#### SUPRAVAGINAL HYSTERECTOMY AND PANHYSTERECTOMY.

SIR,—Your issue of December 1st, in the report of a meeting of the North of England Obstetrical and Gynaecological Society (p. 1045), contains an abstract of a paper by Dr. Fletcher Shaw on the above subject. "He said that some gynaecologists believed that panhysterectomy should be done whenever the uterus had to be removed." As one who holds that belief and has exclusively practised panhysterectomy for twenty-three years, I should like to make a few comments on his paper, so far as I can judge it by the abstract.

Dr. Shaw has had, in a period of eighteen months, three patients in whom cancer of the cervix occurred after supravaginal hysterectomy, "although," he adds, "these cases were the only ones he had ever had." The important point is not whether he had had other cases, but whether other patients whose uteri he had amputated had had the disease and had taken their cases elsewhere. I have recently seen a case of carcinoma of the cervical stump twelve years after supravaginal amputation of the uterus for myoma by another gynaecologist. May I ask how many consecutive cases of supravaginal hysterectomy Dr. Fletcher Shaw has seen and examined after twelve years? (Dr. Chisholm's case shows that it may occur even after twenty-five years.)

Is Dr. Shaw, who has in fact had three cases in eighteen months, justified in saying that malignant disease of the cervical stump is "very rare"? No less than 276 cases have been collected from American sources alone. It formed 6.5 per cent. of all the (123) cases of cancer of the cervix admitted to the Massachusetts General Hospital in a period of five years (1917-22).

I have personally seen six cases, of which four had been operated on by other gynaecologists and two by myself. My two cases occurred amongst thirty amputations (6.6 per cent.), and caused me to give up the operation last century.

The superiority of total hysterectomy over amputation has been emphasized in recent years by Polak and Mayo in America, Döderlein, Bumm, and Franz in Germany, Weibel in Vienna, and de Ott in Petrograd. I have performed it consistently for twenty-three years. Dr. Shaw asked his hearers if they had had cases of cancer in the cervical stump. Of the five who replied three had had cases (two in nulliparae) and two did not remember. The president, Professor H. M. Phillips, however, believed that panhysterectomy was the better operation in all cases.

If Dr. Fletcher Shaw had acted on the advice I gave in 1916 (*Proc. Roy. Soc. Med.*, vol. x), and had performed total hysterectomy instead of amputation, he would not have had those cases of cancer of the cervical stump to record. In the same volume and in vol. xi I published three papers showing the superiority of panhysterectomy:

\* See also my first paper, "Total Abdominal Hysterectomy for Fibroid Myoma Uteri," *BRITISH MEDICAL JOURNAL*, October 11th, 1902.

but my view received no support either from the president or any other gynaecologist except Mr. Malcolm. Now I am glad to have the support of the President of the North of England Obstetrical and Gynaecological Society. I shall hope some day to have the support of the Manchester school, and, in order to encourage them (especially my friend Dr. Clifford), I may add that in my opinion the total operation, properly performed, has a lower mortality and is in all important respects superior to amputation. Amputation of the uterus is, in my opinion, an operation which should not be performed, and unless it ceases to be performed—and it is being done every day—I do not say your columns will be filled with the records of cases of cancer of the stump, for all will not have the courage of Dr. Shaw and publish them; but many women will lose their lives as a result of that specious but unsatisfactory operation.—I am, etc.,

London, W., Dec. 2nd.

HERBERT R. SPENCER.

### DIFFICULT MIDWIFERY IN GENERAL PRACTICE.

Sir,—I am glad to see in your correspondence columns a letter which shows that I am not alone in feeling that experience of midwifery in general practice does not accord with the very serious pronouncements of the eminent obstetricians and gynaecologists whose opinions and teaching have been published in the JOURNAL during the last few weeks.

Being still in touch with many general practitioners who, like myself, have been in practice for the past twenty or thirty years, I have so far failed to find anyone prepared to admit the practical possibility of carrying on, with the severe restrictions, specially in the use of forceps, which are now pronounced to be necessary: Dr. Vincent Norman's quotation, "if the head does not descend with gentle traction, perforation of the head should be performed," is by itself a killing criticism; my teachers—all, alas! passed over: Dr. Herman, Dr. Cullingworth, and later Dr. Drummond Maxwell—would, I feel sure, never have admitted the necessity for such a confession of impotence.

Although in gynaecological practice one does see not infrequently serious tears, with consequent disabilities, these are not, in my opinion and experience and that of many friends, inevitable, and even if they do sometimes occur they are remediable, while life cannot be restored to an infant destroyed to make the obstetrician's job easier.

While I make no plea for force as a universal remedy, I am sure that the majority of medical men of large experience will remember scores or hundreds of cases in which force, applied intermittently without compression as one can do with axis-traction forceps, proved to be certainly the greatest power for good in the doctor's armamentarium. I venture very humbly also to question the necessity for the comparatively frequent performance of version now advised; with an ordinary breech presentation, while the danger to the infant is very slightly increased in comparison with a vertex, this danger is very small if delivery is properly managed and not hurried by efforts at traction; version of course has its application for delivery when used in appropriate cases of pelvic deformity.—I am, etc.,

London, N.W., Dec. 2nd.

CORAM JAMES.

Sir,—I was more than interested in Dr. Vincent Norman's letter. I entirely agree with all that he has to say. Only last week I delivered, with forceps, single-handed, out in the country, a patient with an unreduced occipito-posterior presentation. Certainly I had rather a hard pull, but I secured a healthy child and the patient made a perfect recovery. Had I read Dr. Luker's remarks previously I am afraid it would have upset all my confidence. Midwifery is a practical art and should be taught by practical men; and the less we read of purely textbook difficulties, and operations that require performing once in a generation, the better for the patient and ourselves.—I am, etc.,

Devon, Dec. 2nd.

J. J. BROWN, F.R.C.S.E.

Sir,—General practitioners who complain of the hard things said about the treatment of some cases of difficult midwifery in general practice seem to be inclined to think that specialists who read papers on the subject have no grounds for the statements which they make. There are some points worth their consideration. No one who has read a paper on difficult labour in general practice has been so foolish as to suggest that the majority of general practitioners did their midwifery work badly. A doctor who takes the trouble to attend British Medical Association meetings at which obstetrical matters are discussed is not likely to be so careless or haphazard in his methods as to warrant the strictures which are sometimes passed on his less careful brethren.

Another point is that the readers of such papers have the best grounds—namely, that in their hospital work they have to try to repair the damage which has been inflicted by unwise methods of delivery. There must be something wrong or we should not see patients maimed or dying from the treatment of conditions in which ante-natal examination and appropriate treatment would have resulted in both mother and child surviving undamaged. When a prolonged pull with the forceps has failed to deliver and the child is dead, it is undoubtedly better to perforate the head and to deliver without injury to the mother than to persist in attempts to drag out the child with the forceps, with the almost certain result of severe damage to the mother, or to deliver by the very dangerous method of version after the forceps has failed. The manipulation necessary in this method of delivery is likely to cause severe injury to the mother and a great risk of sepsis. I have recently seen a case in which the following occurred in a young primigravida: Occipito-posterior position, unsuccessful attempt at manual rotation, prolonged pull with the forceps, version, delivery of a dead child, complete rupture of the perineum, death of the mother from general peritonitis. These tragic occurrences are mostly avoidable, and a member of a hospital staff who comes in contact with them is not "throwing stones" if he does his best to point out the way to avoid them.—I am, etc.,

London, W., Dec. 3rd.

HENRY RUSSELL ANDREWS.

### THE USE OF BUTYN.

Sir,—Like cocaine, butyn is not an anaesthetic which can be used haphazard, and though its danger is probably less than that of cocaine the recognized dosage should be adhered to, and Dr. E. Watson-Williams's warning should not be forgotten—"caution is required in using butyn." It should not be administered in association with cocaine or other local anaesthetics, but there is no objection to adding adrenaline.

Experiments have shown what is the minimum lethal dose with small animals, but at present the amount is not known in the case of human beings. In a letter I have received from Professor Roger Adams of the University of Illinois—one of the joint inventors of butyn—he informs me that of the five deaths which have occurred from its use "no details could be obtained from the doctor" in one case.

"In one other case only," he says, "was a death reported where butyn alone was used, and this was when a very large amount was injected intraspinally. In the other three cases there was a combination of troubles which were probably an important factor in the deaths, although butyn was given as the primary cause. In particular, two of these deaths, reported by a well known eye, nose, and throat specialist, may be mentioned. When these deaths occurred two men from the Abbott Laboratories immediately went to the place where they occurred. In both cases morphine and butyn were used, and the attending nurse reported that cocaine was also used. I mention this latter fact because in the American Medical Association report no mention was made of the fact that other drugs were used with the butyn in these particular cases. An autopsy showed that one of the patients had a severe chronic trouble and the other patient, although no autopsy was made, was not a strong individual. Since it has been shown that administration of several drugs of this kind tends to increase the toxicity to the patient, it seems unfortunate that greater care has not been used in reporting the details connected with each death.

"The Abbott Laboratories have had a continuous fight to prevent surgeons from using too large amounts of butyn. It is not claimed that butyn is non-toxic, but it is claimed that it is less toxic than cocaine in man, and has a greater anaesthetic effect. The inclination of the careless surgeon has been to use amounts corresponding to those that he might use of novocaine, in spite of the warning given in the circulars describing the use of butyn."

**SHOP, LIMITED,** Manufacturers 48, Spelman St., London, E. 1, Chemists,

Dr. Burdick, President of the Abbott Laboratories, informs me that he was present at the autopsy of one of the fatal cases and that "it was probably due to endocrine disturbance, as the autopsy showed enlarged thyroid, persistent thymus (the patient was a boy of 15), disease of one adrenal, enlargement of the mesenteric glands, etc." Regarding the use of butyn in intraspinal anaesthesia, the weaker anaesthetics seem to be sufficient, and neither cocaine nor butyn is required. Nevertheless, Dr. Babcock of Philadelphia, who is probably the leading advocate of intraspinal anaesthesia in America, is employing the latter with much satisfaction.

In conclusion, it is claimed that although like cocaine butyn has some degree of toxicity, yet with ordinary care it may be used with safety, always remembering that smaller doses are required than in the case of the older anaesthetic.—I am, etc.,

Bath, Dec. 2nd.

## TWO SOLECISMS.

SIR,—At a time when all pious citizens are devoutly considering the respective demerits of Protection and the Capital Levy as cures for unemployment it may seem frivolous to look up words in Liddell and Scott's *Lexicon*. However, on so doing I find that *σολοικισμός* means incorrectness in the use of language, *σολοικος* using provincialisms, and that the verb is used of one who errs against good manners. Martial uses "soloeccismum" for a mistake, or a slip of any kind.

The word occurs in a similar context in Juvenal, and in *Anthologia Graeca* of orators using uncouth words and gestures. Liddell and Scott mention only to reject the statement that the word means a provincialism.

Addresses on letters seem no more important than names on brass plates or on farm carts. The truth is we have no regular mode of addressing each other either by mouth or in writing. Only in the last fifty years has the title "esquire" become general. Anyone conversant with the literature of the last age will bear me out in this. Again, we have no general word for a medical man, such as "médecin" in French. "Leech" is obsolete. Surgeons now are all great operators, and physicians folk who write prescriptions. My father, who has been dead nearly fifty years, was known (in the country) as "Lawyer X." to distinguish him from a neighbouring farmer of the same name. I believe that in private barristers always address judges as "judge" without further addition, although in court "Your Lordship" is the proper phrase, and I have heard that bishops are addressed in the same way by their intimates (if such there be). The rector of a parish or the warden of a college is usually addressed on letters as "The Rev. the Rector of Blankton," "The Rev. the Warden, . . . College," but in private as "Rector" or "Warden." Many people still address letters to the clergy as "The Rev. Mr. Brown, the Vicarage, Blankton," and though I cannot lay my hands on it, I have a recollection of a letter addressed to "Mr. (=Master) Dr. Latimer," the Reformer.

As to the familiar address "Good morning, doctor," I can produce a parallel from Arabic—"Ya hawadji," meaning "Thou merchant," and many visitors to Egypt have received demands for backsheesh under this term.

Perhaps after all, these matters may be left to wait till we have settled Protection, the Capital Levy, Panel practice, and the peace of Europe.—I am, etc.,

November 25th.

OBSCURUS.

SIR,—May I ask to whom the remarks of the letter of "Suum Cuique" in the JOURNAL of November 24th (p. 1006) are addressed? Surely the "you" which is used several times cannot refer to yourself as editor or to members of the medical profession as JOURNAL readers! The "you" and the "wine merchant, lawyer, and housewife" seem incompatible.

Regarding habit No. 1—how should we address the doctor? Surely not plain "Smith" or, if we remembered his Christian name, "John Smith"? The "John Smith, Esq.," which "Suum Cuique" seemed to hint at would certainly not be correct in these days when the majority of doctors are no more squires than other hard-working folk.

If "Suum Cuique" made the contents of the letter a little less intricate we might be able to understand his point of view.—I am, etc.,

November 24th.

SEDGE.

SIR,—Your correspondent "Suum Cuique" has hit the nail, but not right on the head. The truth is that "Doctor"—or the abbreviation "Dr."—is in reality an academic and not a professional title. It implies the holding of a doctor's degree, whether in medicine, science, philosophy, divinity, or music. Strictly speaking, it ought not to be applied to a medical man unless he holds the degree of M.D. Custom gives it to anyone holding a medical qualification, but in such case it is only a courtesy title, and the qualified physician who does not hold the M.D. degree ought not to call himself "Doctor," whatever his friends may do.

A somewhat analogous case occurs in the use of the term "Esquire." This should be applicable only to landed proprietors, though it is now applied indiscriminately to every man holding any social position at all. But to call oneself "Esquire" or to put it on one's visiting card would be the action of a "bounder"—it is purely a courtesy title.—I am, etc.,

November 27th.

SCIENTIAE DOCTOR.

SIR,—"Suum Cuique" has fallen into the common—or shall I say vulgar?—error of supposing that the word "doctor" connotes a medical practitioner.

Doctor is, of course, the highest degree granted by a university, in the faculty of medicine amongst others. It is, therefore, perfectly correct to address the possessor of this degree, both verbally and in writing, by the title "doctor." Indeed, a failure in this respect is a distinct breach of the amenities.

"Doctor" ranks with "colonel," "major," "general," etc., as an honourable title. It does not indicate the holder's profession; in this respect it differs from the examples given above. My remarks do not refer to the use of the title "doctor" by medical practitioners who have not a university degree.—I am, etc.,

Salford, Nov. 25th.

STANLEY HODGSON.

\* As often happens, this correspondence appears to be drifting away from the points raised by our original correspondent. It is, of course, true that the title of "Dr." cannot be limited to the medical profession, since universities grant doctorates in other faculties. It is also true that the title of "Dr." is commonly applied to medical practitioners, even though they do not hold a university degree. In 1903 the Association decided that practitioners other than graduates in medicine and surgery were not justified in styling themselves "Dr."; but at the Annual Representative Meeting in 1913 the matter was reconsidered and the resolution of 1903 rescinded. This action was taken after the Royal College of Physicians of Ireland had resolved that a Fellow, Member, or Licentiate of that College might, by courtesy and usage, call himself "Dr.," but had no right to use the letters "M.D." or call himself "Doctor of Medicine," unless he held that degree from a university. In 1912 the Royal College of Physicians of London modified one of its by-laws which had forbidden a Fellow, Member, or Licentiate of the College to assume the title of "Dr." or append to his name the title of "Doctor of Medicine," or the letters "M.D." or any letters indicating that he was a graduate of a university, unless he had obtained a degree entitling him to do so. The modification was the omission of the words "assume the title of Dr. or."

## VACCINATION PROPAGANDA.

SIR,—The great flaw in Dr. Killick Millard's argument is his assumption that every attack of small-pox in an unvaccinated person would be so severe as to lead to immediate diagnosis. Experience in the North and Midlands proves, however, that even in unvaccinated people the disease may be so mild as to be unrecognizable by the general practitioner. If, therefore, the whole population were unvaccinated it does not appear that we would have any greater

protection against diffusion of infection, by early diagnosis of mild cases.—I am, etc.,

Laden, E.C., Nov. 30th.

T. F. MANNING.

SIR,—One has always rather admired Dr. Killick Millard, but he is now shown to be even more admirable than one thought. A man, and a medical officer of health into the bargain, who after (1) side-slipping, and (2) plunging into a mirage, finally (3) "still stands on his head"—such a man has unwonted stuff in him. It makes one proud to be an M.O.H.—I am, etc.,

Bracegrove, Nov. 30th.

H. CAMERON KIDD.

#### EPSOM COLLEGE.

SIR,—It is again my duty to bring before your readers the good work carried out by the Royal Medical Foundation of Epsom College, which consists of (a) giving pensions of £50 a year to fifty aged and impecunious medical men or their widows; and (b) providing, free of charge, a high-class education, together with clothing, maintenance, and pocket money, for fifty necessitous sons of medical men.

To enable these beneficent objects to be carried out the Council have had to supplement the moderate income derived from invested funds by procuring contributions from medical men and others amounting to over £6,000 a year. It is necessary to obtain this large sum from subscriptions and donations owing to the greatly increased cost of food, clothing, lighting, heating, wages, repairs, and general expenditure. Furthermore, Epsom College, like other secondary schools throughout the country, has had to incur a heavy additional expenditure in masters' salaries, while a more costly masters' pension scheme has recently been instituted in order to attract the best masters to the College.

I therefore urge all friends of the College to do what they can to assist the Council to procure the further financial support needed, by increasing their own subscriptions for a few years, and by bringing the good work of the Foundation before medical men and others.

The Foundation has strong claims on the public, bearing in mind the services rendered by the medical profession in the prevention of disease as well as in the treatment of illness and accidents. It frequently happens that, owing to the exceptional risks to which medical men are exposed, permanent disablement and even premature death occur in the course of the discharge of their everyday duties. The Council have received numerous applications for assistance as a direct consequence of the war, and Foundation Scholarships and Salomons Entrance Scholarships have been awarded to several boys whose fathers were killed in action or lost their lives in torpedoed vessels. But these Scholarships, together with the Council Exhibitions, very inadequately meet the calls for aid in forwarding the education of many very necessitous and deserving sons of medical families.

The Pensioners and Foundation Scholars are elected in June each year by the votes of the Governors, who are allotted ten votes for every guinea subscribed annually, and ten votes a year for life for every donation of ten guineas.—I am, etc.,

HENRY MORRIS.

Honorary Treasurer of Epsom College  
and its Royal Medical Foundation.

November 30th.

#### PUERPERAL MORBIDITY.

SIR,—With the authority of the honorary surgical staff of the Jessop Hospital for Women, Sheffield, I beg to make the following statement in reply to the criticism of Dr. Gibbon FitzGibbon in the BRITISH MEDICAL JOURNAL for November 24th (p. 1004) levelled at their interpretation of the British Medical Association standard of puerperal morbidity in the report for 1922.

Their method of arriving at the morbidity rate is carefully defined in the report as including "all cases in the first eight days with a rise of temperature over 100° F. occurring twice in twenty-four hours and excluding the first day," and the rate is given in percentages of deliveries to exclude fatal cases and also to include them.

Substituting the word "reaching" for "over" before

the figure 100° F. in the above definition, then the morbidity rate, including fatal cases, works out at 10.3 per cent. as against 7.9 per cent. in the published report for 1922.

It is debatable as to whether Dr. Gibbon FitzGibbon's interpretation of the words "on any two of the bi-daily readings from the end of the first to the end of the eighth day after delivery" as given in his letter but not in the Rotunda Hospital Report, or that given in the Jessop Hospital Report, is the correct one. If the former, then the morbidity rate for 1922 should read 11.6 per cent.—I am, etc.,

J. ERIC STACEY, M.D.Lond., F.R.C.S.Edin.,

Registrar, Jessop Hospital for Women, Sheffield.  
Sheffield, Dec. 4th.

#### THE RIVIERA.

SIR,—I am writing to impress on the medical profession that the French Riviera, to which patients may be sent during the coming winter, is not, as the textbooks teach, a marine climate. It is essentially a mountain climate, in that during the winter the air passes almost continuously at night, and during nearly all fine days (and most days are fine), from the mountains to the sea. The sea-fronting hotels are, climatically, as remote from the sea as those more inland. Patients needing moist, soft, soothing seaside air will find it at Biarritz, or on the Cornish Riviera, but not on the French Riviera, where the air is dry, fresh, and stimulating.

This letter was called forth because I have lately purchased an English book on treatment, which classes the French Riviera with Bournemouth and Torquay, and says that, because of the sea air, it is "apt to disagree with those who have inactive livers." Starting from false premises, the conclusion is false. For inactive livers, as also for catarrhal conditions, whether bronchial, aural, or intestinal, the Riviera is pre-eminently suitable. The malady often disappears without any professional help.—I am, etc.,

Mentone, Nov. 27th.

D. W. SAINWAYS.

#### Obituary.

G. DUNCAN WHYTE, M.D.EDIN., M.R.C.P.LOND.,

Examiner in Medicine, Hong-Kong University.

GEORGE DUNCAN WHYTE, who died at Hong-Kong on November 25th, will be remembered by a large circle of Edinburgh men who graduated about 1900. He was a remarkable man, and even those who knew him least will recall the unmistakable characteristics of his rapid walk and his still more rapid talk. But those who knew him intimately—and they were perhaps few—recognized in him one quality above all: he was indomitable. His sense of duty was always driving him along, and it would be difficult to name a student of his time who contrived to pack so much activity into his undergraduate career. He certainly did more than his share of public work, and his earnestness in study was only equalled by his enthusiasm for clinical work. While he did not achieve many prize medals he kept up a remarkably high average in his classes. Indeed, those who knew him best realized that if he had been a "pot-hunter" he could have collected a remarkable series of honours. But Duncan Whyte was an all-round man at work. He had always intended to be a missionary, and he kept before him an ideal of all-round efficiency that precluded half-heartedness even in the least interesting subject. If he excelled in one subject more than another it was perhaps anatomy, when he became a demonstrator and prosector to Sir William Turner.

In 1902 he joined the English Presbyterian Foreign Mission and sailed for Swatow. His value and efficiency as doctor and surgeon, as teacher and preacher, can easily be guessed by those who knew the man, his spirit, and his equipment. In 1913 he received a gold medal for his M.D. thesis on "An epidemic of cholera treated by intravenous saline injections." But this was merely one indication of his all-round professional efficiency. It was impossible to mention any department of therapeutics in which he did

## The Vicary Lecture

ON THE

## LIFE AND TIMES OF WILLIAM CLIFT,

FIRST CONSERVATOR OF THE MUSEUM OF  
THE ROYAL COLLEGE OF SURGEONS

OF ENGLAND.

GIVEN IN THE THEATRE OF THE ROYAL COLLEGE OF SURGEONS,  
FRIDAY, DECEMBER 7TH, 1923.

BY

SIR ARTHUR KEITH, M.D., F.R.S.,

CONSERVATOR OF THE MUSEUM.

On the 14th of February, 1792, the household of John Hunter, on the east side of Leicester Square, was the scene of two events. In the first place, his master's birthday was being celebrated; sixty-four years before he had been born on the farm of Long Calder-

wood, situated within sight

of the smoke of Glasgow,

In the second place, a

country lad, William Clift,

had arrived from Bodmin,

in Cornwall. Probably no

one in the household knew,

or cared to know, that the

day of his arrival was also

William Clift's birthday;

he was born at Bodmin on

February 14th, 1775, and

this on the day of his

arrival in Hunter's house

had just completed his

seventeenth year. He was

a poor lad; all he possessed

in the world were the

clothes he stood up in,

with "four changes of

shirts and neckcloths," un-

less we add certain inden-

tures which he is said to

have carried in his pocket,

wherein Hunter had under-

taken to teach him, "in his

best manner," to draw,

write, and dissect. It is

difficult to believe that

Hunter could have made a

promise about writing and

drawing, for he could not

draw and his writing was

indifferent, whereas Clift

was already a skilful

draughtsman and an ex-

quisite penman.\*

Thus in this household in

Leicester Square we have

brought together, from

Scotland and from Cornwall,

men of diverse ages whose

lives were destined to be linked

together in an altogether

peculiar manner. The bond

between them was soon to be broken; Clift had only served

his master for twenty months when the catastrophe at

St. George's Hospital left him stranded in Hunter's

derelict Museum. For fifty years Clift remained the

honest steward of the great collection which Hunter left

behind, and the undaunted upholder of his name and

fame.

There was more than a mere coincidence of birthdays

to link these two men together. As Clift aged, those who

had known Hunter saw in him a remarkable physical

likeness to his master. Both were small, active men;

Hunter's height was only 5 ft. 2 in. To those who insin-

ated that this likeness was due to more than a coincidence

Clift would reply: "If I thought what you insinuate were

true there is not a Duke in London I would touch my

hat to."

\* A list of the documents and publications from which the facts given here have been drawn is added at the end of this lecture.

WILLIAM CLIFT.  
First Conservator of the Museum of the Royal College of Surgeons of England.  
Appointed 1800; retired 1822. Died 1843.  
(From a Lithograph in the Conservator's Room at the College.)

I gladly avail myself of this opportunity of acknowledging my indebtedness to Mrs J. S. Collins of St. George's Hospital, who has supplied me with many details relating to Bodmin, and to Mrs. Gilbert, through my friend Mr. Walter Rogers of Bournemouth, has presented a water-colour sketch of Bodmin Castle to the Hunterian album kept by the Librarian of the Royal College of Surgeons. To Mr. Victor Plarr, the Librarian, I am deeply indebted for his placing the manuscripts in his keeping, and for his placing the portrait of Clift in the College there are preserved a lithograph and a water-colour of Clift and also a portrait bust, done in 1822.

Before following young Clift to the place he was to occupy in Hunter's household we must turn aside for a moment to trace his early life in Bodmin. His birth-place—a flour mill—was swept away when the London and South-Western Railway built its station in the valley about one mile to the west of the centre of the town. But the little stream which turned the wheel of Burcombe Mill is still running; there are still men and women who remember the old dilapidated millhouse.† In 1775, when his youngest son, William, was born, the affairs of the miller, Robert Clift, were hastening from bad to worse; he had to leave the mill, and three years later died in Bodmin at the age of 88, leaving his wife, Jeanne Courtes, and his family, in poverty. The widow and daughters earned a scanty and precarious livelihood by carding and spinning wool in the winter and by working in the fields in other seasons—each member earning from fourpence to sixpence a day. "My mother," says Clift, "starved herself to save threepence a week for my schooling."

Then in 1783, when Clift was eight years of age, his mother died, and thus, to use his own words, "I was cast adrift on the wide wide world." He did not drift very far; he entered the service of Mr. George King, a nurseyman at Bodmin, at fourpence a day. Mr. King was given to brandy and water, or as Clift expressed it, "to brandy without water," and in his cups, and after them, was passionate and dangerous. In one of these fits, some two or three years after Clift entered his service, he chased, while mounted on horseback, his nimble-footed apprentice from the nursery. The young man and fellow workmen merry by producing a graphic caricature of the apprentice made his fore-noon. The young man and fellow workmen merry by producing a graphic caricature of the apprentice made his fore-noon. The young man and fellow workmen merry by producing a graphic caricature of the apprentice made his fore-noon.

Thereupon obtained further employment in Bodmin with one thing to do with him. He "George" would have any-George "King or King as he put it, "neither Mr. thought of enlisting, but a wide wide world." He himself "admit in the young Clift again found made him so angry that to Mr. George King it incident, but when shown graphic caricature of the man and fellow workmen merry by producing a graphic caricature of the apprentice made his fore-noon. The young man and fellow workmen merry by producing a graphic caricature of the apprentice made his fore-noon. The young man and fellow workmen merry by producing a graphic caricature of the apprentice made his fore-noon.

men, and to this Clift was no exception. Issues the stream which flows by Burcombe Mill. In Clift's Near by Bodmin Church is the Priory; from its grounds to this Clift was no exception. makes men seek for service rather than for command. Men of his nature are often the hardest judges of their fellow men, and to this Clift was no exception.

not show a practical knowledge of the most recent developments. To his hospital and medical college he used to take with him after each furlough not only the very latest appliances and apparatus, but also a thorough knowledge gained by strenuous study in the months that should have been given to relaxation. But he never learned how to relax; it was almost as if he had known from his student days that his life was to be cut short in its prime, and as if that sense of pressing haste and strenuous activity arose from such a source. Some of us who took our Hippocratic oath with him may live to hoary old age, but it is unlikely that, even so, any will achieve what Duncan Whyte crowded into the twenty-three years of his professional career.

In 1922 he came near to death by sprue, and reached this country in a serious condition. He improved, and persistently minimized his symptoms. He was soon doing post-graduate bacteriology when he should have been resting. Finally he sailed early in October to return to his post; but soon became seriously ill. At Colombo he was already in danger; he reached Hong-Kong, and soon after landing he died. One of the deepest regrets of his life was that his Mission Board refused to give him permission to serve with the R.A.M.C. during the war. Had he done so, and had he fallen in France, he could not have given his life more directly than he has done in the cause of humanity. Those who had the privilege of his intimate friendship will know that there will never be another quite like George Duncan Whyte.

H. C. M.

Dr. WILLIAM GOWANS of South Shields died on November 15th, aged 77. He was a native of Galashiels, and took the diplomas of L.R.C.P. and S. Edin. in 1868 and F.R.C.S. Edin. in 1883, and graduated M.D. Durh. in 1886. Soon after qualifying he went to South Shields and took charge of the old dispensary, now merged in the Ingham Infirmary, with which institution he was associated for many years as honorary surgeon and subsequently as consulting surgeon and vice-president. He continued to practise in South Shields up to the time of his death. Dr. Gowans was elected a member of the British Medical Association in 1870, and served as president of the North of England Branch, and from 1912 to 1915 was chairman of the South Shields Division. He was also a former vice-president of the Durham Medical Society. He was appointed to the Commission of Peace in 1892, and took great interest in the volunteer movement, having served as surgeon and afterwards as commanding officer of the 3rd Durham Volunteer Artillery; he retired with the rank of lieutenant-colonel. During the war Dr. Gowans had six sons holding commissioned rank, and he received a letter from Buckingham Palace expressing the King's appreciation of the patriotic spirit which had prompted them to give their services. One son died of injuries received during the war. Two other sons are members of the medical profession—Dr. Thomas Gowans, ophthalmic surgeon to the Ingham Infirmary, and Surgeon Commander Francis J. Gowans, R.N. The funeral took place on November 17th, and was attended by several members of the bench and the medical profession, as well as by representatives of institutions with which Dr. Gowans had been connected.

We regret to record the death on November 21st, at the age of 63, of Dr. ARTHUR JALLAND STILES, of Spalding, Lincolnshire. He had been for some time in ill health, and his death, though sudden, was not altogether unexpected. The family of Stiles has long been connected with the Spalding district. Dr. Thomas Stiles practised for many years in the village of Pinchbeck, two miles from Spalding, and lived there to the age of 97. He was succeeded by his son, Dr. Henry Tournay Stiles; he was a widely known and respected medical practitioner, and was the father of Dr. A. J. Stiles and of Sir Harold Stiles, Regius Professor of Clinical Surgery in the University of Edinburgh. Dr. Arthur Stiles received the early part of his medical education at University College, London; afterwards he entered at the University of Edinburgh, took the degrees of M.B., C.M., with distinction in 1883, and the M.D. with commendation in 1886. After graduating he joined his father at Spalding and, when Dr. Henry Stiles died at the age of 83, remained

at the old home, taking a partner and continuing to practise for five years. He then retired, but retained his interest in the affairs of the district with which his family was so long identified. He was J.P. for Holland, a member of the Holland Standing Joint Committee, a governor of the Spalding Grammar School and the Spalding High School for Girls, a trustee of the Spalding Johnson Hospital, and a member of the Spalding Town Husbands, having the administration of the principal charities of the town. He was at one time chairman of the Divisional Liberal Association and at the time of his death was a vice-president. He was a considerable owner of property in the town and district, and a keen horticulturist. At one time he took a keen interest in growing bulbs for the market; he afterwards gave this up but still made his garden his hobby. The funeral, which took place on November 25th at Pinchbeck, where four generations of Stiles rest, was of a semi-public nature. It was attended by a large gathering, including many leading residents and his brother, Sir Harold Stiles.

Dr. ARTHUR WILLIAM HARE died from pneumonia at Gateshead on November 22nd, aged 62. He was the son of the late Samuel Hare of Darlington, and received his early education at Oliver's Mount School, Scarborough. After a very distinguished student career at the University of Edinburgh, he graduated M.B., C.M. with honours in 1882; and in 1886 he took the diplomas of M.R.C.S. Eng. and F.R.C.S. Edin. He became resident surgeon at the Edinburgh Royal Infirmary and assistant at the University under the late Professor Chiene. He continued his studies at Leipzig, Berlin, and Vienna, and in 1888, at the early age of 26, was appointed professor of systematic and operative surgery at Owens College, Manchester, and surgeon to Ancoats Hospital; but owing to a breakdown in his health he had to resign those posts five years later. On returning from travels in America, Hare settled at Newquay, Cornwall, and practised there for more than fifteen years. On the outbreak of war in 1914 he offered his services to the War Office and, receiving a temporary commission as lieutenant in the R.A.M.C., was stationed at Devonport. For the past seven years he had been assistant medical officer of health and school medical officer for Gateshead. Though handicapped always by indifferent health, he had been able to carry on his work until within a few weeks of his death. During the early and brilliant part of his professional career, Hare wrote frequently on surgical, anatomical, and pathological subjects. While at Edinburgh he collaborated with Sir G. Sims Woodhead in a work on *Pathological Mycology*, and he made a number of contributions on cranial surgery to encyclopaedias and medical journals. He leaves a widow and three daughters.

Mr. G. T. BROOKSBANK JAMES, who died of cancer on November 15th at the age of 56, gained the entrance scholarship at the Westminster Hospital Medical School, and subsequently acted as house-surgeon there, and as clinical assistant at the Westminster Ophthalmic Hospital. He became a Fellow of the Royal College of Surgeons in 1896, and later ophthalmic surgeon to the Westminster Hospital, and to the Royal Eye Hospital, Southwark. In addition to his London practice, he developed a further considerable one at Eastbourne, where he was ophthalmic surgeon to the Princess Alice Memorial Hospital. James was a well read man and a good conversationalist with wide and varied interests. His fitness for the work of an ophthalmic surgeon was exhibited in his patient dealings with cases of refractive error and in the skill he showed when operating for chronic glaucoma. He was always prepared to enter upon a discussion over minute details concerning the establishment of a filtration which would persist. That he was well acquainted with the literature of his special subject is shown by the fact that the Section of Ophthalmology appointed him the representative on the Library Committee of the Royal Society of Medicine.

Dr. FRANÇOIS HELME, a well known contributor to the *Presse médicale* of articles concerned with the welfare of the medical profession, has recently died.

Priory that Hunter had lost the services of William Bell—his draughtsman, amanuensis, and assistant in the Museum. In 1789 Bell, who had been in Hunter's service for fourteen years, had accepted a surgeoncy in Sumatra, and although three years had come and gone since his departure Hunter could find no one fit to become his successor. It was upon Mrs. Gilbert's recommendation, that this Cornish lad, earning some tenpence a day, had struck home in Cornwall he was suddenly transported to one of the most remarkable households which London has ever seen—to become the worthy successor of William Bell.

Winter's House and Museum.

The household in which young Cliff now found himself an inmate stretched from Leicester Square eastwards to Castle Street—now converted into Charing Cross Road. Our intimate knowledge of the shape and size of the establishment we owe to Cliff; forty years after he first entered it he sat down late one night and drew a ground plan on which are entered all details relating to Hunter's house. The property which Hunter had acquired in 1783, with a lease which had only twenty-four years to run, was built on a long narrow strip of ground only 30 feet wide. Every- upon a strip of ground which stretches from a main street to a back lane; the house faces the main street, the garden occupies the space between. Hunter's establish- ment was built on the same plan. The house, facing Leicester Square, had four tall windows on its drawing room or first floor, where Mrs. Hunter, her sixteen hair turning grey, entertained the select literary and artistic circle in which she moved. The second and third floors—bedroom floors—had also their four windows; the ground floor had only two windows—dining room and windows—for the front door with Hunter's plate was to the visitor's right as the house was approached. The door opened into a commodious hall—where the butler had his chair. Passing through the hall one entered a passage leading along the ground floor of the house to the garden or yard; to the right and left of this passage or back hall were Hunter's consulting room and his study—rooms with which Cliff was to become familiar. At the Castle Street end in place of stables there was a roomy dwelling, where Hunter's five house-pupils had quarters, and where Elizabeth Adams presided as housekeeper. As time went on she came to take an important part in Cliff's life. Here was the dissecting room and quarters for Robert Haynes, who looked after it and the lecture room, and here, too, was Cliff's abode. In the garden or yard stretching from the one house to the other, about 110 feet in length and 30 feet in width, Hunter had erected a building with an inside measurement 51 feet long and 28 feet wide. The ground floor was divided so as to serve as a reception room towards the Leicester Square end and a lecture room towards the Castle Street end. The lofty upper floor of this building served as a Museum; round it ran a gallery on the shelves of which stood Hunter's wonderful collection of physiological preparations—the part of the Museum which became Cliff's special pride. From the gallery a fossil or cabinet room opened off. The Museum did not occupy the whole length of the garden or yard; between it and the house on Leicester Square (No. 28) there was room for the building in which Hunter kept his collection of drawings and prints and where his artist worked. The space between the Castle Street house (No. 15) and the eastern end of the Museum was enclosed by a glazed roof, covering the sunken basement or conservatory where Hunter kept his six horses. To coaches, and the skull of a large whale-bone whale. To reach the Castle Street level the coachman had to drive up

*Life in Hunter's Houschold.*

*Life in Hunter's Houseshold.*  
Critt found himself a member of a very large establish-

floor there was the butler, the housekeeper (Mr. Hunter), the Welsh cook (Mary Edwards), Mrs. Hunter's housemaids, and the needlewoman. William gently became acquainted with the kitchen; and wrote of this period: "I knew there was plenty but no pocketing; Mrs. Martin (the housekeeper) too sharp after all but her own friends." The stables there was Mrs. Hunter's coachman as footman as well as Mr. Hunter's coachman and in the drawing room there was the tall and elegant Hunter; for her and for Miss Hunter (after Campbell) Cliff acquired and retained an unbounded devotion. Miss Hunter had her visiting-eleven Then, in vacation times, there was also young from learning expensive habits in St. John's College. Workmen and tradesmen kept coming all day long.

house; we must now turn to its professional far as they concerned William Clift. The dinner was cleared at 9.30 sharp, as patients began to leave their consulting room until 11 o'clock. Hunter was busy in his carriage half an hour before he came to see his hospital and his private patients, hoping to get home again for dinner at 4, and have time for his evening work. With this part of the day's work over, he went to his master's study in the Castle Street premises, not without his master's duties as surgeon, there was a special secretary, with his quarters in the street house, to look after army affairs. It was about 7.30 in the morning when I called on him. He had been up since 6.30, and had finished his work for the night. He had a very good dinner, and was in excellent spirits. He had been thinking much of late about his life, and was particularly interested in the history of his family. He had been reading a great deal of history, and was particularly fond of the lives of the great men of the past. He had also been thinking much of his own life, and of the many things which he had done. He was a very thoughtful man, and was always ready to listen to what others had to say.

## Universities and Colleges.

### UNIVERSITY OF OXFORD.

The following candidates have been approved at the examination indicated:

D.P.H.—Part I: J. G. Johnstone, A. A. E. Newth, H. Shannon, A. C. Tibbitts. Part II: W. H. Butcher, H. W. Hardy, A. A. E. Newth, H. Shannon, A. C. Tibbitts.

### LONDON INTER-COLLEGIATE SCHOLARSHIPS BOARD.

ELEVEN medical entrance scholarships and exhibitions of an aggregate total value of £1,134, tenable in the Faculty of Medical Sciences of University College and King's College, and in the Medical Schools of King's College Hospital, University College Hospital, the London Hospital, and the London (Royal Free Hospital) School of Medicine for Women, will be offered. The examinations will commence on April 23rd and June 24th, 1924. Full particulars and entry forms may be obtained from the Secretary of the Board, S. C. Ranuer, M.A., the Medical School, King's College Hospital, Denmark Hill, London, S.E.5.

### SOCIETY OF APOTHECARIES OF LONDON.

The following candidates have passed in the subjects indicated:

SCROGAY.—J. R. Coache, J. E. Elam, S. Halperin, J. B. Sweet, S. Thompson.

MEDICINE.—J. E. Elam, E. J. R. MacMahon, W. McLaren, D. Parsons, L. "Lain" Grosch.

FORENSIC MEDICINE.—J. E. Elam, D. Parsons.

MIDWIFERY.—P. V. Collins, E. J. Creais, J. T. Elam, E. J. R. MacMahon, W. McLaren, I. Morgan, D. Parsons, F. H. Ratnagar, M. A. L. Somers, J. B. Sweet, E. W. Wain.

The diploma of the Society has been granted to Messrs. J. E. Elam, E. Halperin, D. Parsons, M. A. E. Somers, and S. Thompson.

## The Services.

### AWARD OF C.B.

THE King has appointed Surgeon Commander William Percival Hingston, R.N., to be a Companion of the Order of the Bath (Military Division), "in recognition of the gallant conduct displayed and the valuable services rendered on the occasion in September last of the destruction by earthquake and fire of the R.N. Sick Quarters, Yokohama, when by his gallantry and presence of mind he was the direct means of saving the lives of the large number of refugees who sought escape from the fire in the hospital grounds."

### DEATHS IN THE SERVICES.

Inspector-General Thomas Lyle Horner, R.N. (retired), died at Plymouth last month. After taking the L.R.C.P. and S. Edin. in 1853, he entered the navy as surgeon, attained the rank of deputy inspector-general on March 9th, 1893, and retired, with an honorary step as inspector-general, on October 1st, 1903. He was medical officer of the old battleship *Dreadnought* when King George was serving on her as Lieutenant and Prince Louis of Battenberg was her commander.

Surgeon Major Alfred Lewer, R.A.M.C. (retired), died in London on September 29th, aged 85. He was born at Wimborne, Dorset, educated at King's College, London, and took the M.R.C.S. in 1853, the L.S.A. in 1859, and the L.R.C.P. Edin. in 1850. Entering the army as assistant surgeon in 1853, he served in the Royal Artillery till the regimental system was abolished, became surgeon-major on January 21st, 1874, and retired on May 23rd, 1891.

## Medical News.

THE following have been appointed Knights of Grace of the Order of the Hospital of St. John of Jerusalem in England: Lieut.-Colonel Gerald Hamilton Goddard, D.S.O., R.A.M.C., Dr. Hugh Falconer Oldham, M.B.E., and Lieut.-Colonel William Booth Skinner, D.S.O., S.A.M.C.

At the annual meeting of the Scottish Women's Hospital Association of the Royal Free Hospital on December 1st it was announced that the Duchess of York had accepted the presidency of the Association. As a war memorial of the Scottish Women's Hospital it has been decided to endow four beds in the Royal Free Hospital, and the endowment plate for the first of these, to be called the British Macedonian Expeditionary Fund Bed, was formally presented by General Sir George Milne and accepted by Mr. Langton on behalf of the hospital.

THE fourth medical salon will be held in Paris from March 2nd to 9th, and, like the three previous salons, the first of which was held in 1909 and the last in 1912, will contain pictures, sculpture, engravings, etc., which are the work of medical men and pharmacists. Further information can be obtained from the founder and general secretary, Dr. Paul Rabl, 84, Rue Lecourbe, Paris, XV.

SIR HUMPHRY ROLLESTON, K.C.B., M.D., has accepted the chairmanship of the Propaganda Committee of the National Association for the Prevention of Tuberculosis.

SIR THOMAS BARLOW, Bt., who has been elected president of the National Temperance League—the first medical man to occupy that position—attended a meeting of members and associated workers last week, when speeches of welcome and congratulation were delivered by, among others, Mr. McAdam Eccles, Mr. Arthur Evans, and Dr. Basil Price, C.M.G. Sir Thomas Barlow gave an address, in the course of which he dealt with Professor Starling's recent book *The Action of Alcohol on Man*. It departed, he said, from impartial presentation, by the general implications it contained in favour of the ordinary use of alcohol on grounds other than scientific.

At a meeting of the West Kent Medico-Chirurgical Society to be held at the Miller General Hospital, Greenwich, on Friday, December 14th, at 8.45 p.m., the Purvis oration will be delivered by Sir Thomas Horder. The subject selected is carcinomatosis.

THE autumn dinner of the Irish Medical Schools' and Graduates' Association was held at Pagani's Restaurant on November 27th. Sir William Taylor presided, the guest of the evening being Surgeon Vice-Admiral Joseph Chambers, C.M.G., Medical Director-General R.N. The members of the association and their friends—over a hundred all in all—spent a pleasant evening, enjoyed a good dinner, listened to some excellent speeches and to some delightful Irish songs. It is to be hoped that an even larger number will meet at dinner on next St. Patrick's Day.

A COURSE of post-graduate lectures will be delivered at the Cancer Hospital (Free), Fulham Road, S.W.3, weekly during January, February, and March, 1924, dealing with various aspects of cancer. Medical practitioners and students may attend without tickets. The syllabus of the lectures will be published in due course.

DR. HAROLD SCURFIELD will give his presidential address to the Maternity and Child Welfare Group of the Society of Medical Officers of Health on Friday next, December 14th. The address, which will be on the lines of advance in maternity and child welfare work, will be delivered at the house of the Society, 1, Upper Montague Street, Russell Square, W., at 5 p.m. Members of the profession interested in the subject are invited to attend.

PASTEUR day in Paris, when collections were made for the better equipment of laboratories in France, yielded, it is stated, 13 million francs.

TWO lectures on graphic methods in heart disease will be delivered by Dr. John Parkinson in the Anatomical Theatre of the London Hospital Medical College on December 17th and 19th, at 4.30 p.m. The lectures, which will be illustrated by lantern slides, are intended for senior students of the hospital and post-graduates, to whom a cordial invitation is given.

THE annual report for 1922-23 of the Livingstone College, Leyton, bears witness to the benefit derived from instruction in medical matters as part of the general missionary training. During the last thirty-one years 752 students have received the full training of the college; of these 482 remain at work mainly in districts of Africa, India, and China, where the invaliding and death rates are higher than in any other missionary field. Not only are those so trained enabled themselves better to withstand the dangers of disease but they are able to train others to help in such work as the preventive and curative treatment of leprosy and other diseases. This latter point was emphasized at the College Commemoration Day on June 13th by Sir Leonard Rogers, C.I.E., F.R.S., who spoke very highly of the value of the training supplied by the institution. Additional testimony was given on this occasion by old students of the college who had been working in South India and Nigeria, and in the annual report there are letters from missionaries in Rhodesia, Bechuanaland, and Nigeria expressing similar appreciation of the medical training they had received.

PROFESSOR BIEDL of Prague recently delivered the first Harvey lecture in New York, his subject being organotherapy.

THE Nobel Prize for Chemistry has been awarded to Dr. Fritz Pregl of the medical faculty of Graz.

PROFESSOR BARD, who left Lyons to occupy the chair of clinical medicine at Geneva in 1900 and was nominated professor of clinical medicine at Strasbourg at the end of the war, has returned to Lyons to succeed Professor Teissier. He is succeeded at Strasbourg by Dr. Prosper Merklen.

DURING the recent earthquake in Japan the houses and all the property of eight professors of medicine were destroyed, but none was killed. The Tokyo University library was completely destroyed by fire during the earthquake.

To do this he has spared no pains. He has gone to the four winds of heaven in search of knowledge. His choice has ranged from the imposing blue books of the Meteorological Office to the common Bradshaw of the railway bookstalls. And by dint of perseverance extended over many years he has succeeded in compiling a veritable encyclopaedia—and an encyclopaedia arranged so well as to enable any item to be found at a moment's notice. Commencing with a general introduction on geology, climatology, and the physiological effects of meteorological factors, he passes on to a description of the climate of the British Isles as a whole, followed by a more detailed account of each of the seven districts into which he divides England and Wales. In these chapters, which are meant for reference rather than for continuous reading, besides affording information as to geology, temperature, sunshine, cloud, rainfall, relative humidity, snow, hail, fog, gale, thunderstorm, and prevalent winds, he includes a description of the various towns, health resorts, and spas, with useful data as to their social and recreational amenities. In conclusion he discusses the therapeutics of the English climate, and indicates the localities which are likely to prove most beneficial to sufferers from particular diseases. Two appendices are provided, the one a seasonal therapeutic guide to the health resorts, the other a classified list of waters at the various spas. An index of unusual clarity completes the volume. Perhaps the most valuable feature of the book is the attractive collection of coloured charts, which are intended to convey at a glance information concerning the various climatic factors in the area under consideration. In this their success is such as adequately to recompense the author for the relatively enormous labour he must have expended in their compilation.

As for criticism, there is little to be said, but we should like to make one or two suggestions. In the next edition, which will probably be called for rapidly, we would welcome the inclusion of a few maps. It is impossible to read the book intelligently without the aid of an atlas, and we feel it would be an advantage if, perhaps, two or three general and a dozen or so district maps could be supplied, just to refresh one's memory of the geography of the places under discussion. The section dealing with the effects of climate on the human organism might very well be enlarged. At present it covers only two pages and gives but a summary of the subject. Would it not be wise to include the recent work of Leonard Hill on the effects of temperature, winds, and humidity; that of Rollier, and of Miss Chick and her co-workers, on the effect of sunshine; to dilate upon the results of exposure to heat and cold of varying degrees—in fact to dwell more fully on the changes wrought by the physical conditions of the atmosphere? There is no book of which we know that treats of these subjects comprehensively, and it is in a volume of this nature rather than in one of general hygiene that the reactions of the climate upon the body should be described.

But enough! The present edition is excellent. And it has fulfilled its function of affording data which cannot be obtained elsewhere in a single volume. It would be understating the case to say that the book carries our recommendation. It does more. It leads us to assert that it is a book of such value that it should find a place on the desk of every practitioner—consulting and general alike. Only when used daily as a handbook of reference will it be appreciated at its full value, and only when it is appreciated at its full value will the author be repaid for the extraordinary diligence and care which he has bestowed upon it.

#### ENCYCLOPAEDIA MEDICA.

THE ninth volume of the second edition of the *Encyclopaedia Medica*<sup>1</sup> has a melancholy interest, for it brings again to our minds the premature death of Dr. J. W. Ballantyne, who so successfully brought out the first eight volumes in the face of many difficulties, and appears to have done some of the labour entailed by this volume, at any rate he revised his articles on "Maternal Impressions" and "Midwives." In

his place the publishers have obtained the services of Dr. ALEXANDER GOODALL for the completion of this and the remaining volumes which it is hoped will all be brought out before the end of next year. This is, perhaps, rather optimistic, as the present volume, dealing with articles in alphabetical order from "Mammillaplasty" to "Obesity," still leaves a considerable field to be covered.

The volume contains new articles on military surgery by Sir D'Arcy Power, neurasthenia by Dr. Ivy McKenzie, and mycetoma by Major W. S. Patton; the articles on diseases of the muscles, nursing, and obesity have been rewritten by Mr. Tubby, Miss White, and Dr. D. Murray Lyon respectively. The account of the anatomy, physiology, vascular disturbances, inflammations, tumours, and some other conditions of the meninges has been revised by Dr. George Riddock, and the late Sir William Osler's account of cerebro-spinal fever by Dr. Claude B. Ker, who points out that a meningeal reaction due to serum sickness may, unless this possibility is borne in mind, be regarded as a relapse of the disease, but that in such a case the cerebro-spinal fluid will be found to contain a normal amount of glucose, whereas this is much diminished or entirely absent in the original attack and a relapse. There are nine articles on the nose and its diseases, Mr. Logan Turner's description of the inflammatory affections of the accessory sinuses being illustrated by some fine plates. In his article on nephritis Sir Nestor Tirard adopts with modifications Dr. John Gaskell's classification of the forms of nephritis, and refers to war nephritis and the tests for renal function. Dr. J. S. Browne's article on natality, or birth rate in its relation to population, is concise, suitably supported by statistics showing the widespread decline of the birth rate as a result of a search for "voluptuous sterility," and quite definite as to the need for a substantial remission of the income tax based on the number of children. Among the numerous short unsigned articles there is a judicious account of masturbation.

Altogether this instalment worthily maintains the standard set up by its predecessors, and we wish the new editor a continuation of his initial success.

#### THE "NAUHEIM" TREATMENT AT HOME.

THE sixth edition of Dr. LESLIE THORNE THORNE's book on *The "Nauheim" Treatment of Diseases of the Heart and Vessels in England*<sup>2</sup> contains some new matter dealing with the treatment of arterio-sclerosis, alternation of the heart, and auricular fibrillation. The balneological treatment of heart disease has been received with a certain degree of scepticism in this country, and no doubt much of the discredit which attaches itself to it has been due to the over-zealous claims put forward and to the commercial advertising which has been adopted to impress the doctor and the layman and to attract him to the Continental spas. The author of the volume before us endeavours to demonstrate that the results claimed for the method are not dependent on residence in a foreign country, nor due to the mode of life adopted at the health resort, but can be equally well secured in any private house which has a bath and a supply of hot water. The general principles underlying the action of the baths and the method of administration are dealt with in a simple and explicit manner in the opening chapter. Great stress is laid on the necessity for selecting a bath suitable for the condition to be treated, as the author considers that failure to obtain a satisfactory result is in many instances due to giving an effervescing bath when a still bath is indicated.

All classes of heart and blood vessel disease would appear to be benefited by this line of treatment. Many cases are described and charts are given of the cardiac dullness and also polygraph tracings both before and after treatment. The cases of cardiac dilatation seem to have reacted in a most remarkable way, and the cardiac dullness as illustrated by the figures in the text has been reduced from an area which in some cases extended from well to the right of the sternum to the nipple line, to an area almost less than the

<sup>1</sup> *Encyclopaedia Medica*. Second edition, vol. ix, "Mammillaplasty to Obesity." General Editor, Alexander Goodall, M.D., F.R.C.P.E. Edinburgh and London: W. Green and Son, Ltd. 1923. (Roy. 8vo, pp. x+672; 15 figures, 9 plates. 30s.)

<sup>2</sup> *The "Nauheim" Treatment of Diseases of the Heart and Vessels in England*. By Leslie Thorne Thorne, M.D. Sixth edition. London: Baillière, Tindall, and Cox. 1923. (Post 8vo, pp. vi+232; 135 figures, 7s. 6d. net.)

which was at once gratefully accepted. By 1803 Home had been elected to the Court of Assistants, and was naturally appointed a member of the Board of Curators, and thus acquired a dominant influence in the affairs of the Museum. He set Clift down to compile catalogues of all sections of Hunter's Collection; these catalogues were mere lists of contents, but were drawn up with great care and written into folio volumes with meticulous accuracy. Home was too busy looking after his hospital, his practice, and the output of scientific and professional papers to take any part in the work of cataloguing.

#### *Board of Trustees.*

In the summer of 1805, on a Saturday afternoon, the Trustees, appointed by Parliament to see that the College of Surgeons carried out the conditions attached to its trust, met for the first time. The Trustees inquired about catalogues and about lectures, and were told that the College had already spent £2,547 on the Collection, and that, as the lease of the Castle Street Museum was almost up, the College had bought for £4,600 Mr. Jenner's house (No. 42) next door to the College House (No. 41) on the south side of Lincoln's Inn Fields as the site of a new Museum. It was resolved by the Board of Curators not "to make the narrow finances of the College the measure of their proceedings." I suspect the phrase is Home's; at least in seeking Government aid to build a new museum, just as on the occasion of the purchase of the Collection by the Government in 1799, Home was chief ambassador in the transaction.

#### *Building of the New Museum.*

The houses on the south side of Lincoln's Inn Fields, where the Corporation of Surgeons sought a home in 1796, were built on the same plan as Hunter's house in Leicester Square. The strips of land on which the houses had been erected stretched from Lincoln's Inn Fields in front to Portugal Street behind; the strips were wider but not quite so long as the site on which Hunter had put up his Museum. The College house was No. 41; the next house to the west (No. 42) became the Museum house—where Clift was ultimately to live—and its garden was the site on which the new Museum was to be built. In the spring and summer of 1806 Clift moved the Hunterian Collection from Castle Street\* and stowed it safely away in the rooms of the Museum house, until the new building was erected behind; it was not until 1813 that the new Museum was finished and opened to visitors. The conservator's chief duty was to conduct visitors round the Museum twice daily and explain its contents to them. Of this daily duty Clift never tired.

#### *Everard Home as Master.*

In 1808, in his 42nd year, Everard Home was appointed Sergeant-Surgeon to the King; he was elected in 1811 to give the first course of lectures on comparative anatomy; the Board of Trustees begged him to publish the lectures, but he modestly declined. Then in 1813, having become Master of the College, a baronet, and having given a second course of lectures, he acceded, with all diffidence, to a renewed request from the Hunterian Trustees to publish, and succeeded in persuading the Board of Curators to spend £165 of the College money on their distribution gratis. It was in the year of his Mastership that the Prince Regent paid a visit to the Museum; a scarlet cloth was spread at the gateway for the reception of the royal visitor. Home's colleagues on the Board of Curators complained that they had not received due notice of so distinguished a visit. The Master excused himself on the ground that the honour was altogether unexpected, leaving his colleagues perplexed to explain the foresight which had provided a scarlet cloth of reception for the occasion.

#### *Renewed Demands for a Catalogue.*

The Board of Trustees kept urging the need of supplying proper catalogues for the Museum. In 1816 Sir Everard's colleagues on the Board of Curators were resolving to

divide the Museum into sections, each member undertaking the task of preparing a catalogue for one department. At this meeting of the Board Sir Everard struck an attitude and demanded that the duty and honour of preparing catalogues must be his and his alone. He made the Conservator arrange an important section of the Museum, wrote a short guide or synopsis for this section, and in the meantime (1817) resigned from the Board of Curators and was elected to the more influential Board of Trustees. He did not in any way lose his prestige in the Court of Assistants, for in 1821, when this body became known as the Council of the College, they elected him to be their first President. Then in 1822 he resumed the Hunterian professorship and gave a course of lectures which his colleagues on the Board of Trustees begged him to publish. He humbly submitted; two more folio volumes on comparative anatomy were issued, rich in plates prepared from Clift's drawings. Again the Board of Curators purchased volumes for distribution.

#### *Burning of the Manuscripts.*

It was in June, 1823, just over a century ago, that Clift helped to correct the last proofs of these two handsome tomes of Hunterian lectures. In the spring of this year Sir Everard Home placed certain fossil bones, discovered in caverns near Plymouth, at Clift's disposal for description and publication. Clift gave a very accurate description of them which was read before the Royal Society. Just after this paper was read Home championed the election of William Clift to the Society; on May 6th, 1823, this act of justice was done to Clift—he became F.R.S. We have several letters which show the relationship which existed between Home and Clift at this time: "My dear Clift, Will you dine with me to-day and read over your paper—on the Plymouth fossil bones?—Yours truly, Everard Home." (November 1st, 1822.) "My dear Clift,—I wish you to attend my lecture at the Hospital on Tuesday at 12. Let me have the coloured prints of the blood and the sections of the aneurysm for Tuesday." (January 3rd, 1823.) Sir Everard still held, in the relationship between the two men, the place of patron and master.

On a summer afternoon, July 26th, 1823, Home was driving in his carriage to Kew with two companions—one was William Clift, the other was Robert Brown the botanist and discoverer of the nucleus. They were to attend a small and select society named the Medico-Botanical, of which Home was the leading light. Looking at Clift, Home announced that the night before firemen had forced their way into his house, because his chimney was on fire; he went on to explain that the damage had been done while burning Hunter's papers. "You don't mean," said Clift to the baronet, "you have burned Hunter's manuscripts." Home said he had done as he said; to which Clift relates that he made this reply: "Then, you may as well set fire to the Museum too." One would have supposed that the atmosphere in this coach driving towards Kew would have become sultry, but apparently nothing more happened, and the Medico-Botanicals met and parted as usual. On Home's side there was no trace of a breach, for we find him on September 23rd—two months later—still addressing the conservator, "My dear Clift, You are to be here (Sackville Street) on Saturday at one. Brown and Bauer have already been told, so you have only to write to Aiton." Clift adds a note to this letter saying he was unable to attend on this day. In November it was still "My dear Clift." At this juncture, August, 1823, Sir Everard's co-executor—Dr. Matthew Baillie—died. He never knew the fate which had overtaken Hunter's manuscripts, exactly thirty years after their author's death.

#### *William Clift Turns on Home.*

Clift, on returning from Kew, took an early opportunity of telling the chairman of the Board of Curators, Sir William Blizard, Hunter's old pupil, what had happened to the manuscripts. Nothing was done then; the first step was taken in February, 1824, when Clift was called in by the Board of Curators, which included Cline, Norris, Astley Cooper, Abernethy (Clift's particular friend), Anthony Carlisle, and Lynn. Clift enumerated the manuscripts, and

\* Mrs. Adams, the house-keeper, refused to move; Clift had to obtain an order from the Board telling her to do so, and also that "she was to take her orders from the Conservator." She died on April 22nd, 1812.

rightly held them to have been an intrinsic part of Hunter's Collection and essential for the preparation of a real catalogue. A month later (March 5th) the Board requested Sir Everard to hand over the manuscripts which they had just learned were, or ought to be, in his possession. On March 9th Sir Everard replied that he had destroyed the manuscripts because they were unfinished and unfit for the public eye; further, he had extracted from them and published all that was essential; and finally, that he had closed his thirty years' executorship by destroying them, which, so he wrote, Hunter had instructed him to do! On March 16th the Board replied to Sir Everard that it could not believe that which his words seemed to imply, and again demanded the MSS. On March 22nd Sir Everard informed them that Hunter had made two last requests to him—one, that his body should be examined; the second, that his manuscripts should be destroyed. In the meantime Clift, who knew the inner affairs of the Sackville Street house almost as intimately as those of his own, had learned that there were still some Hunterian manuscripts in existence. So, on April 6th, the Board of Curators addressed a third letter to Sir Everard, saying that they "had good reason to believe" that he had still Hunterian MSS. in his possession. To this third letter Sir Everard replied, three days later, that he declined further correspondence with the Board of Curators. So the Curators carried, "with painful reflections but in pursuance of duty," the matter to the higher authority, the Board of Trustees.

#### *Sir Everard Home is Tried—and Let Off.*

On May 24th, 1824, about six weeks after the correspondence just mentioned took place, the Trustees held a special meeting—ostensibly to consider the preparation of proper catalogues for the Museum. Lord St. Helens was in the chair; Mr. Peel and many other distinguished public men were present. Sir Everard, being a trustee, was also present. He laid the correspondence with the Board of Curators before his fellow Trustees, and begged that it should be entered on their minutes. The Trustees then decided to confer with the Board of Curators, Home having the grace to withdraw when this conference was being held. After the Curators retired he returned, and on being questioned replied that he had destroyed the manuscripts as a duty but he was willing to offer all possible help in the preparation of catalogues. He did help in a small degree, for at the next meeting of the Trustees, on November 27th, he sent a sealed packet, which, when opened, was found to contain descriptions of about fifty of Hunter's own accounts of *post-mortem* examination of cases. At the following meeting, on February 19th, 1825, another sealed parcel came with a like series of Hunter's *post-mortem* records. Clift began to think "the phoenix might yet arise from its ashes," but no more came then. It was at the February meeting, just mentioned, that Sir Everard informed the Trustees. "The Conservator feels himself so outraged at my destroying these papers that he has not only complained to the Board of Curators but asserts that in my whole life I have never done him one act of kindness. In the face of this declaration I beg to state that through me he is now in possession of £1,370 in the 3 per cents." We have already seen how Clift had more than earned this sum. The transaction reflects Home's clever business ability, and at the same time the lengths he was prepared to go to crush one who had given him thirty years of faithful service.

#### *Sir Everard Home's Death.*

In his diary for August 31st, 1832, Clift makes this entry: "Reported at the Board of Curators that Sir Everard Home died this morning at half-past three, at his house at Chelsea Hospital; 77th year; of Scots extraction; born at Hull Dec. 6th, 1756. *Sic transit gloria mundi.*" Then, in another entry, he alleges that the glowing eulogium of Home which was pronounced at the Royal Society on the occasion of his death was written by the deceased gentleman himself! Six weeks after his death young Sir Everard Home, Captain of H.M.S. *Racehorse*, handed Robert Keate, the ex-President of the College, a bundle which was found to contain Hunter's famous folio volume on *The Natural History*

*of Vegetables*, and also ten separate manuscript fasciuli. Seven years later (February 14th, 1839), when young Home entered the theatre to hear Edward Stanley deliver the Hunterian Oration, he handed Robert Keate, again the President of the College, another sealed packet. This contained Hunter's folio volume on *Fossils*, wherein we learn that Hunter had been thinking forty years ahead of the geologists of his time. The open page in the Reynolds portrait tells us that he was seventy years ahead of his contemporary anthropologists. Alas! no further discovery of Hunterian MSS. had to be reported.

#### *What was Home's Motive?*

What motive led Sir Everard Home to commit such an act of vandalism? Clift supposed, and his supposition has usually been accepted, that it was to keep the public from discovering how many discoveries and observations Sir Everard had stolen from Hunter's manuscripts. I do not believe this to be the true reason. We have seen, in his correspondence with the Board of Curators and Trustees, that he not only admitted but claimed as a merit that he had extracted and published all that was of value in Hunter's manuscripts before burning them! We have seen that Home was vain, ambitious, extremely conventional, and orthodox in his beliefs. Hunter was the exact opposite—he was heterodox; there were in his writings statements which would have made the hair of the orthodox stand on end if all his works had been published in 1793. Home declared they were unfit for the public eye, and we may safely infer that he counted Hunter as in error when he was heterodox—Home himself saw the dire fate which overwhelmed William Lawrence when he spoke out his true thoughts concerning man's relationship to animals in the theatre of the College in 1816. Home, fearing the contumely which would descend on Hunter's memory, as well as on the reputation of his living executor, thought he was doing his old and wayward master a true service when he destroyed his unpublished manuscripts. It was vain stupidity—a dangerous possession—rather than criminality, which lay at the root of Sir Everard Home's crowning act of vandalism.

#### *Conclusion.*

In 1827 Richard Owen, only 23 years of age, came to Clift's rescue and showed all the world how a catalogue should be written of a great collection of Comparative Anatomy. There is no space in which to tell how James Paget came in 1842 to render a similar service for the pathological side of the Museum. Richard Owen married Miss Clift, and his father-in-law's self-confidence declined as his own grew. Clift's nerve was sapped by the tragic death of his wayward son from an accident in the autumn of 1832. The father hoped to see his son his successor. When the Board of Curators—by then known as the Museum Committee—met on June 7th, 1842, Clift, who was now in his 67th year, was left standing at the door while Owen went in to help in the transaction of business. Clift was presently informed that his salary of £400 per annum was to continue for the rest of his life, that he was to move out of the Conservator's quarters in the College, and that Owen was to move in. He retired to Stanhope Cottage, near Mornington Crescent, off the Hampstead Road, and there, on June 20th, 1849, he died in his 75th year. His wife died six weeks before him. Richard Owen had inscribed on his tomb in Highgate Cemetery: "He carried a child-like simplicity and single-mindedness to the close of a long and honoured career." Faith in himself may have waned, but his faith in Hunter was never shaken.

The data of this lecture have been drawn from the following records and books:

Sherborn Papers in the R.C.S. Library; contains a fragment of Clift's autobiography.

ing—in other words, to liberate; this accounts for the sudden drop of temperature which occurs in the early stages of the morning often accounts for acute exacerbations of chronic bronchitis in the aged, and it is important to prevent them from this by keeping the temperature of the room at a suitable level, but overheated rooms and over-lying are to be strongly deprecated. I am convinced that custom of keeping chronic bronchitis in over-heated rooms is largely responsible for keeping up and increasing its susceptibility to changes of temperature. Gradually it becomes (it is not too old and feeble) to living and using in comparatively cool rooms, and you will do much to restore their resistance to cold—just as happens in cases of phthisis when submitted to open-air treatment. A house in a southern aspect, and not surrounded by trees, should be selected.

As regards the treatment of chronic bronchitis generally, it is of the utmost importance to recognize the underlying condition of which bronchitis may be merely a secondary symptom. The irritable winter cough of elderly people is frequently associated with definite gouty or rheumatic local measures to counteract the diathesis. Such cases can derive much benefit from a course of treatment by x-ray and inhalations at Mont Dore, also at Harrogate, the habit of deluging the unfortunate patient with drugs and expectorant variety is happily rapidly dying out, and their place the use of vaccines has become the vogue. I would like to emphasize the necessity of having the culture can direct from the patient at a pathological laboratory—this is not possible, that means should be taken to treat the culture war or spasm. For if it becomes led, the organisms causing the catarrh will fail to develop in culture. With this precaution I think many of the cases could be avoided. As a prophylactic measure to prevent the patient against acute exacerbation of the catarrh, think vaccines are of considerable value.

The method of continuous inhalation of dry vapours, or the method of Burrey Lee, or the various forms of porters, often gives very definite relief, especially where associated with a tendency to bronchial spasm. But this is in the direction of asthma, which would require in more time than the whole allotted to this discussion. I should like to draw attention to the value of dry cupping over the bases in the treatment of acute or subacute emphysema, especially when the bases become engorged and dyspnoea and cyanosis become pronounced and the right side of the heart embarrassed. This method is universally practised on the Continent, but has fallen into disuse in this country. The relief it gives is often quite minute.

—MICHAEL G. FOSTER, O.B.E., M.A., M.D., CAMB., F.R.C.P. (LOND.), Harrogate.

Climatic Treatment of Chronic Bronchitis.

I have been asked to devote myself to the climatic treatment of chronic bronchitis. Part of the ground has been already traversed by Dr. Hyla Greaves; I would, therefore, confine my remarks to treatment abroad. As in every disease, the first question with which we are confronted is: Can the disease be arrested? To my mind the consideration has been given to those cases which are drifting into chronic, or, in the strict sense of the term, into chronic bronchitis. A man between 35 and 45, who is probably suffering from colds from his youth onwards, begins every winter or spring attacks of cough with expectation; year by year these attacks become longer, the cough more persistent, the sputum harder to expectorate; the moral being that there is slight increase of mucus with each winter.

He becomes increasingly careful, avoids night air, suffers up; the general upshot of his codding is in the

I can call to mind a very distinguished man in the scientific world who thirty years ago had such constant attacks of winter cough that his friends were anxious as to whether he could continue his duties. He went for a month or two to the Engadine for two or three years, and now, hard on 70, is in robust health and full activity. The season should be undertaken in the winter, first on account of the invigorating effects of dry cold, secondly because the air is drier and more aseptic when the snow is on the ground. Two cautions should be observed: the heart and arteries must be sound, sleep normal, and the chest walls must not show any marked rigidity. The late Dr. Huggard laid great stress on the fact that cases with rigid chest walls never did well in the high Alps; subsequent experience by others has confirmed this dictum. I wish to urge the importance of such a method, and the advantages to be derived from its early employment.

Spa treatment affords another useful method of benefiting these cases. The methods employed are largely variants of that originating from Ems. The procedure consists in spraying the throat with pulverizations of varying fineness, regularly being renewed by working the machine with compressed air, whereby the force can also be adequately controlled.

This treatment is carried out with the same machinery with natural mineral water at English spas—Harrogate, At Mont Dore in Auvergne, which has acquired a great reputation for the treatment of asthmas, a like treatment is carried out by means of sprays of arsenical water. The cure is enhanced by the effects of altitude. Similar methods of inhalation are carried out with sulphur water at Cautelets and Lucbon in the Pyrenees. At Sals Maggiore the patient sits in an atmosphere of finely pulverized bromo-iodine water.

Turning to the next type of case in which bronchitis is firmly established, whether in consequence of persistent winter cough or spasmodic asthma, the position is entirely different. Repeated congestive attacks have largely been different. The bronchial mucous membrane of ciliated epithelium, the bronchi has impaired the elasticity of the lungs; consequently what the French term *retentissement des bronches* is an operation performed with steadily decreasing efficiency. Treatment in such cases must aim at the reduction of irritating qualities in the inspired air with a view to lessening secretion. Warmth and absence of fog are the fundamental requisites; to those for the majority of cases more may be added dryness of the air, though some cases are benefited by a moist climate. It has been a traditional custom to send these cases to the Riviera, to Algiers, Egypt, or the Canary Islands. The value of climate has, from the occurrence of what I may term experimental bronchitis. I refer to the sequelae of gas poisoning. These cases are not of common occurrence, and as far as my observations go are due either to chlorine, or acetylene, or observations of the cases sent to the base in the period July to September, 1918, when—as many of you will remember—some of the cases sent to the base differed from ordinary cases of mustard-gas poisoning. In cases such as these we have examples, not of slow degenerative changes in the bronchi and lungs brought about by years of repeated attacks of congestion, but the whole bronchial tree, previously in a perfectly healthy condition, changed at once into a state like that produced by years of winter cough. The inundational pathological changes in chronic bronchitis is loss of ciliated epithelium. When we reflect on the post-mortem appearances seen in cases of gas poisoning—the spongy mucous membrane of the trachea and the raw bronchi—the pathological analogy becomes apparent. I have been much struck by the influence of the Riviera climate in the cases which have come

## RECURRENT OR HABITUAL DISLOCATION OF THE SHOULDER-JOINT.

BY

A. S. BLUNDELL BANKART, M.C.CANTAB., F.R.C.S.,  
 ORTHOPAEDIC SURGEON, MIDDLESEX HOSPITAL; SURGEON, ROYAL  
 NATIONAL ORTHOPAEDIC HOSPITAL AND HOSPITAL FOR  
 EPILEPSY AND PARALYSIS, MAIDA VALE.

RECURRENT dislocation of the shoulder-joint is an uncommon condition, the real nature of which appears to be little understood. It may almost be said to be peculiar to athletes and epileptics—a rather curious association which, as I shall show, is not without etiological significance. Most of the former class are powerful, healthy, athletic young men to whom the frequently recurring dislocation from trivial causes is a great and serious disability. In epileptics the dislocation sometimes recurs with every fit. The dislocation is nearly always anterior. I have only seen one case of posterior recurrent dislocation. That case was in a woman, and she was not operated upon.

The condition has been attributed to abnormal laxity of the capsule of the joint, and to weakness of the surrounding muscles. The abnormal laxity of the capsule is supposed to be due to stretching or imperfect healing of that structure after the reduction of an ordinary traumatic dislocation, and it has been thought that too early and too vigorous use of the arm may be the cause of the defect.

### Various Operations.

Two types of operation have been performed for the relief or cure of this disability: (1) Operations designed to diminish the size of the capsule. These comprise various folding, plicating, plication, or overlapping procedures, with or without incision or excision of a portion of the capsule. (2) Operations designed to give support to the capsule, particularly at its lowest part where the dislocation is believed to take place during movements of abduction. The most favoured of these operations is that of Clairmont and Ehrlich, in which a strip of the deltoid muscle is transplanted in the form of a sling beneath the joint, and is supposed to contract and hold up the head of the humerus when the arm is abducted.

Both these types of operation are based upon erroneous ideas of the pathology of recurrent dislocation of the shoulder. In the first place, the capsule in these cases is not unduly lax. Had the capsule of the shoulder-joint been normally a lax structure, the more than one surgeon has commented upon the wastefulness of raising a satisfactory fold when doing a plication or excision for recurrent dislocation. Secondly, the muscle of support is not weak. There may be a little wasting after the operation, but any other injury to the shoulder-joint, and the grounds for a musculature that is usually exhibited by these patients, is a sufficient commentary on this point. Thirdly, the joint does not need support below, for it is not here. Cure of the dislocation takes place.

It must be admitted that the operations have sometimes been successful in preventing the recurrence of the

dislocation, but this result has usually been due to limitation of the normal movements of the joint by the operative procedure. One surgeon, indeed, has suggested that the operation might be simplified if it were done deliberately with this purpose, and he proposed to graft a band of fascia between the chest wall and the humerus in order to limit the movement of abduction to 60 degrees.

### Causes of Recurrent Dislocation.

It has been too readily assumed that recurrent dislocation is an unfortunate sequel of ordinary traumatic dislocation, and I have known medical men reproach themselves quite unnecessarily for their treatment of the original injury. Recurrent dislocation has nothing whatever to do with ordinary traumatic dislocation of the shoulder-joint. It is an entirely different injury, and it is produced in an entirely different manner.

Ordinary dislocation of the shoulder is the commonest of all dislocations of the joints. It is caused by a fall on the abducted arm. In extreme abduction the neck of the humerus impacts against the acromion process, and by leverage the head is forced through the lowest and weakest part of the capsule between the subscapularis and triceps muscles. When such a dislocation is reduced, the rent in the capsule heals rapidly and soundly, and the dislocation rarely, if ever, recurs.

But the dislocation which afterwards becomes recurrent is caused, not by a fall on the abducted arm, but by a fall either directly on the back of the shoulder or on the elbow which is directed backwards and only slightly, if at all, outwards. The head of the humerus is forced out of the joint, not by leverage, but by a direct drive from behind forwards. In its passage forwards the head shears off the fibrous capsule of the joint from its attachment to the fibro-cartilaginous glenoid ligament. The detachment occurs over practically the whole of the anterior half of the glenoid rim. The reason why the dislocation recurs after reduction is that, whereas a rent in the fibrous capsule heals rapidly and soundly, there is no tendency whatever for the detached capsule to unite spontaneously with the fibro-cartilage. The defect in the joint is therefore permanent, and the head of the humerus is free to move forwards over the anterior rim of the glenoid cavity on the slightest provocation.

In quite a number of the cases the original injury is stated to have occurred at football, and it should be noted that in this game, at least, a player is seldom sent sprawling with his arms out, but, when he falls or is thrown to the ground, it is usually in some moment of strenuous action, when his muscles are tense, and his arms are more or less close to his sides. Usually he is too preoccupied to make much attempt to save himself, and in falling backwards he is likely to strike either the back of the shoulder or the point of the elbow, which is directed backwards. The epileptic, too, falls with his muscles tensely contracted, and he, of course, makes no effort to save himself. Frequently the arms are drawn backwards and little, if at all, abducted. So that, if he falls backwards, he is likely to strike either the back of the shoulder or the point of the elbow. Thus both athletes and epileptics are liable to sustain dislocation of the shoulder-joint by direct violence rather than by indirect force or leverage.

Some cases have been described in which fractures, either of the anterior margin of the glenoid cavity or of the greater tuberosity of the humerus, have been associated with recurrent dislocation. Such fractures have not been seen in any of my cases, but it is easy to see how they might be caused by the direct force which produces the initial dislocation. They must, however, be regarded as incidental, and not essential, to the recurrent dislocation. The essential feature is the detachment of the capsule from the fibro-cartilaginous glenoid ligament.

### The Operation Recommended.

I have now exposed this typical lesion at operation in four consecutive cases. A satisfactory exposure cannot be obtained by the anterior incision ordinarily employed for arthrotomy and plication operations on the capsule, and

aching and chronic catarrhal rhinitis, and tonsils in childhood, is a very frequent cause of cold-

 projecting front teeth and a markedly gothic palate.  
 obstructed nose and was a confirmed mouth-breather  
 chronic condition. On examination he had a very n-

of bronchitis or bronchopneumonia which supervened  
 his doctors, by nearly died each winter from an acute  
 the fact that he wintered in the places recommended  
 He was sent to me because, despite his careful life  
 his lips bluish.

His heart was acting badly, his complexion very sallow  
 up a large quantity of mucopurulent secretion every  
 had chronic bronchitis for twenty years. He always co-  
 think are worth quoting. A patient between 50 and 60  
 cases, but two cases come prominently into my mind  
 I need not weary you by a recapitulation of a set

bronchitis is established.  
 descending infection gradually progresses until a c-  
 of no symptoms except, perhaps, some catarrh, an  
 ment. In chronic sinus cases the patient may co-  
 and the nose rendered healthy by operative or other  
 the patient is often lucky because the condition is t-  
 the patient becomes blocked and an acute condition super-  
 of the nasal mucous membrane. If the outlet of the in-  
 accessory sinuses. These are, of course, merely an exte-

to spread to infection of the lining membrane of the  
 mucous membrane with acute exacerbations, but is  
 sepsis. This may be limited to chronic infection of the  
 Nasal infection sooner or later generally leads to  
 liable to post-operative pneumonia because the soil is r-  
 of bronchitis or pneumonia. Such patients are esp-  
 infection occurs and the patient succumbs to an acute  
 certain amount of bronchitis. Finally, a specially vi-

no doubt this is the reason why the condition has not been generally recognized. The operation which I have done has been planned to expose completely the anterior margin of the glenoid cavity.

A small pillow or sandbag is placed beneath the scapula, so as to keep it forwards. The arm lies on the table by the patient's side, and it is rotated inwards, so as to relax the pectoralis major muscle. The incision extends from the upper border of the clavicle above the coracoid process downwards and outwards for about five inches. The deltoid and pectoralis major muscles are separated, and the coracoid process and the three muscles attached to it (pectoralis minor, biceps, and coraco-brachialis) are defined. Perthes, who used a similar incision in operating upon fractures of the glenoid, divided the pectoralis major, but I have not found this step necessary. The coracoid process is next divided with an osteotome or bone forceps, and drawn downwards with the three muscles attached to it. Lastly, the tendon of the subscapularis is divided close to its insertion, and this muscle is retracted inwards.

The damaged area is now fully exposed. Internally one sees the neck of the scapula with the fibro-cartilaginous glenoid ligament lying upon it. This ligament has usually been torn up a little way from the glenoid margin, so that it appears as a free edge lying upon bare bone. External to this is the glenoid cavity with the head of the humerus in contact with it. Running from above downwards over the joint cleft is usually to be seen a band of fibrous tissue which represents the free edge of the capsule which has been torn from the glenoid ligament. It appears as a band because immediately external to it is the not inconsiderable and perhaps enlarged opening of the subscapularis bursa. Lastly, external to this is the fibrous capsule of the joint covering the greater part of the head of the humerus. The mechanism of the recurrent dislocation can now be easily demonstrated, for on taking hold of the arm and pushing its upper end forwards, the head of the humerus can be made to pass freely over the anterior edge of the glenoid cavity.

To anyone who has seen this typical lesion exposed at operation it must be obvious that the only rational treatment is to reattach the fibrous capsule to the glenoid ligament whence it has been torn. It is clear that a plication or similar operation performed on some distant part of the capsule can only have the effect of drawing the detached edge outwards and further away from the glenoid margin. No doubt, if the capsule is sufficiently diminished in size, it may prevent displacement of the head of the humerus notwithstanding the defect at the glenoid margin, but this is at the expense of free movement in the joint. It should be remembered that the capsule of the shoulder-joint is normally a lax, and not a tense, structure.

It is exceedingly difficult to believe that operations of the Clairmont-Ehrlich type can have any influence in preventing recurrent dislocation, except by limiting the normal movements of the joint. Even if one could think that the transplanted strip of muscle acted in the way it is supposed to do, it is not clear how this would prevent the dislocation, for the displacement does not take place downwards, but forwards.

In my cases the joint defect has been repaired by interrupted sutures of silkworm gut passed between the free edge of the capsule and the glenoid ligament. It is well to freshen the bone on the neck of the scapula, so that the glenoid ligament may adhere to it. Having repaired the joint defect, the divided subscapularis tendon is reunited, the detached portion of the coracoid process is sutured in place, and the wound is closed. After the operation the arm is kept at rest for four weeks, and then active and passive movements are begun and persisted in until the movements of the joint are normal.

Two of my cases were epileptic, and both the others sustained the original injury at football. One case—a powerful epileptic—had some limitation of abduction two months after operation, and he has not been seen since. This relatively poor result was due to his neglect of after-treatment. The others recovered full movement at the shoulder-joint, and in none of them has the dislocation recurred.

## TREATMENT OF MIGRAINE BY CALCIUM LACTATE.\*

37

A. DOUGLAS BIGLAND, M.A.CAMB., M.D.LIVERPOOL,  
M.R.C.P.LOND.,

HONORARY PHYSICIAN, DAVID LEWIS NORTHERN HOSPITAL, LIVERPOOL;  
LECTURER IN CLINICAL MEDICINE, LIVERPOOL UNIVERSITY.

MIGRAINE, passing under many names and treated by a host of different remedies, is a condition of surpassing interest on scientific grounds alone. To practising physicians the condition is of similar importance for three reasons: (1) Migraine is a very common ill; although referred to by those who have never suffered from it as a minor malady, yet in reality it accounts for an enormous amount of wretchedness and impaired efficiency. (2) Migraine appears to attack with great frequency the professional classes in general and medical men and women in particular. In the literature splendid accounts of the condition have been supplied by doctors who were themselves sufferers, and in my series of twenty cases eight were members of the medical profession or medical students. (3) The old treatment of migraine, as evidenced by the long list of so-called remedies, is not satisfactory. More recently fresh conceptions and new drugs have been tried with some success, and the results obtained with one of these remedies is the justification for this communication.

It appears probable that the fundamental cause of migraine is an anaphylactic shock. How this shock is manifested, and indeed in what particular part of the brain the manifestation occurs, is not known. The accurate, subjective localization of the headache and the external phenomena associated with the superficial temporal artery suggest the area of the brain underlying the squamous portion of the temporal bone as the probable site of the lesion; the occasional aphasia and even rarer hemiplegia met with in migraine point to the motor cortex. On the other hand, the visual phenomena, which are so common, can only be explained by referring the disturbance to the occipital cortex, and the vomiting is possibly associated with the medulla. It has been suggested that the pituitary gland may undergo temporary enlargement and thus cause symptoms, but the type of hemianopsia met with in migraine is opposed to this view. It would appear, therefore, that no single cerebral area can be held responsible for the various phenomena of the disease.

The undoubted relation between eye-strain and migraine is difficult to explain upon an anaphylactic basis unless it be that a brain already sensitized will react unduly to any stimuli and among them impulses connected with the ocular apparatus. On the other hand, the equally well known connexion between migraine and other nervous disorders, such as epilepsy, can best be explained on an anaphylactic basis; these conditions also are considered by many to have a similar origin. On this assumption it is not exactly correct to say that migraine is hereditary, but rather that a liability of the nervous system to become sensitized and react to certain stimuli in themselves innocuous may be transmitted. Migraine in the parents may be represented by asthma or angio-neurotic oedema in the children.

It is remarkable that organic disease, especially perhaps that of the cerebral vessels, is not more often associated with migraine, for temporary aphasias and hemiplegia are comparatively common in the former (Case v).

Of the symptoms occurring in the attack those connected with vision come first in point of time and in importance, since they may be the sole manifestation. A sudden general dimming of vision is a very common prelude, followed by scotomata, coloured dazzling spectra, and hemianopsia. These constitute the aura of an attack and, as might be expected, they are often associated with vertigo. In a short time follows the headache, which is usually localized very accurately to one temple and practically always to one side of the head. The least movement or any temporary increase in intracranial tension, as by coughing, is accompanied by

\* Based upon a note read before the Liverpool Medical Institution on January 4th, 1933.

mucous membrane and its replacement by scar tissue; laryngitis, tracheitis, and bronchitis easily follow. A similar process occurs in atrophic rhinitis and in undue patency due to trauma, operative or otherwise.

Tonsillar infection in adults is, in my experience, less likely to lead to chronic bronchitis than nasal infections. Recurrent tonsillitis and gunitis are apt to lead to chronic ill health and in voice users to laryngitis, with weakness and hoarseness of the voice.

Oral sepsis is undoubtedly a factor in the production of chronic bronchitis, and people of middle age with septic teeth if they have bronchitis.

Hay fever, paroxysmal rhinitis, and asthma are part of a syndrome and can be conveniently discussed together in relation to chronic bronchitis. They can, perhaps, be defined as abnormal reactions to stimuli which affect the upper respiratory tract.

Essentially hay fever is produced by undue sensitiveness to pollen which causes acute congestion, swelling, and secretion of the nasal mucosa.

Many hay fever cases are susceptible to different stimuli, such as mimos, horse chest-nut, tobacco plants, roses, emanations from animals such as horses and cats, as well as the typical cases due to grass pollen. Some of them are susceptible to several of these.

In addition, typical hay fever may go on to typical asthma. In the same way paroxysmal rhinorrhea or vasomotor rhinitis may be caused by difference of temperature, change of posture such as getting up in the morning, and also occurs in hay fever and asthma cases.

The typical asthma case is in my experience more often than not associated with one of the above. Whether the type, chronic bronchitis is very apt to follow. Why is this?

Obviously because swelling and hypersecretion of the mucous membrane of the upper respiratory tract sooner or later allow of infection. In hay fever and vasomotor rhinitis there is at any rate intermittent congestion and obstruction of the nasal mucous membrane with consequent infection.

In these cases the chronic bronchitis, as in cases of primary nasal obstruction, may be and often is a descending infection. The frequent association of nasal polypi and asthma is well known, but it must not be thought that the presence of polypi is the primary cause of the asthma, or that the removal of polypi from the nose will necessarily cure or even alleviate the symptoms.

It is true that the mechanical effect of the polypi may determine the onset of an attack; we must look deeper for the cause. Polypi are an evidence of nasal infection most frequently of the ethmoidal cells and it is this infection of sinuses which follows on the nasal obstruction due to swelling of the mucous membrane of middle turbinates and septum, which produces the polypi and often a descending infection of the bronchi.

The removal of polypi may and often does improve asthma and bronchitis by allowing free drainage from the affected sinuses.

Others more skilled than myself are dealing with the question of infection and immunization of the upper respiratory tract, and I would only suggest the following clinical observations. If a patient coughs up sputum and this is cultured, an idea of the bacteriology of the bronchi may be obtained, but the picture may be obscured by mouth organisms, saprophytes, etc.

In my experience a post-nasal swab will often give the true organism responsible for the condition. In every case cultures should therefore be taken from the gums and post-nasal space, in addition to culture of the sputum. Often Pfeiffer's bacillus may be found in the latter which cannot be got or is obscured in a culture from the sputum.

Similarly a Friedländer infection may be shown by culture from this area uncomplicated by dust infections or casual organisms, which would be found in a culture from the anterior nares. These frequently have no significance in the production of the clinical condition.

In conclusion, I will briefly epitomize the main points on which I should like to lay stress.

1. Many if not the majority of cases of chronic bronchitis have their source of infection in the upper respiratory tract and are descending infections.

2. All cases of chronic bronchitis should have the nose and throat examined from this point of view.
3. Pathological conditions of the nose and throat should be treated.
4. Special attention should be directed to the treatment of nasal obstruction, nasal sepsis, and nasal sinus infections.

#### GENERAL DISCUSSION.

Dr. A. C. LEXAY (London) said that in every case of chronic bronchitis the sputum must be examined as a routine for the presence of tubercle bacilli; also the possibility of a syphilitic infection must always be borne in mind. It was advisable to examine the blood as regards the Wassermann under. In the former infection the treatment with vaccines and the bacillus of Friedländer. In the latter very successful. A possible explanation of this might be found in Professor Dreyer's recent publication of the lipoidal content of the Gram-positive and Gram-negative microbes. The "defatting" might lead to better results from antiseptic treatment. Preventive inoculation should be carried out during periods free from catarrh.

Professor E. L. COLLIS (Cardiff) said that he had investigated records of morbidity and mortality in England and Wales from bronchitis among adults. As a result he found that this disease contributed so much to sickness and death among adults.

It was probably responsible annually for 80,000 years of invalidity, and accounted for some 28,000 deaths at ages of 15 and over. The mortality particularly concerned late life, and was somewhat heavier for males than females. It had been falling rapidly since 1870, and rather more for males than females.

The fall had been greatest where the mortality formerly was high—i.e., in the lower grades of the industrial community. Statistics of mortality due to bronchitis presented the characteristics of a disease entity, varying independently of pneumonia and phthisis. They indicated that bronchitis was conducted to by severe climatic conditions, such as windy weather and more particularly by atmospheric pollution. Industrial work induced bronchitis less than pneumonia or phthisis; and evidence was lacking that aggregation of persons in industry, which represented opportunities for infection, influenced the prevalence of the disease; here in bronchitis differed from phthisis. Occupations, whether due to irritating gases or injurious dusts, carried with them risk of bronchitis. Generally mortality records suggested a chronic traumatic origin for the disease rather than an infectious origin. Reduction in morbidity and mortality from bronchitis might be expected to follow from (a) such social uplift as increased the health of lower grades of society, and from (b) smoke abatement in industrial districts and great towns.

Dr. FLORENCE STOKES (Bournemouth) drew attention to a very common cause of bronchitis in dental sepsis. This might frequently cause no local trouble and could only be detected by x-rays; the dentist and the doctor could see the state of the apices without this help. Even one tooth with an abscess at the apex might be responsible for chronic bronchitis. A child aged 13, who had had bronchitis for six years, was completely cured by the x-rays discovering a hidden apical abscess, which was removed, and the chest condition at once cleared up. Many cases of chronic bronchitis were left with their teeth in a very septic condition.

Dr. ALEXANDER KEY (Southsea) discussed, from the standpoint of the general practitioner, the pathology of the condition, especially as regards the capacity for repair possessed by the damaged mucous membrane. It was this inability adequately to repair the damage which was their chief difficulty and which so often defeated their efforts, and on this account

agonizing pain. Nausea, terminating in retching and vomiting, completes the painful picture. The whole attack may last only a few hours or be prolonged for a day or two. All the stages of the typical migraine attack just described may not be present in any given case. The ocular symptoms alone, or the headache alone, frequently occur, and even nausea and vomiting may be the sole manifestation of an attack (Case III). In the last eventuality grave mistakes in diagnosis may be made.

It will be plain from the formidable list of drugs used in combating migraine how unsatisfactory our treatment is. Following upon accustomed lines the treatment of a paroxysmal malady is best discussed under the headings: (1) measures used between attacks, and (2) measures used during attacks.

#### *Measures Used Between Attacks.*

Under this heading prominence must be given to the importance of correcting refractive errors. There are grounds for supposing that slight errors, which are sometimes regarded by oculists as negligible, may be more potent as migraine producers than are the obvious ones, in which owing to their magnitude the ocular mechanism appears to give up the unequal contest of correction.

Under this heading, too, must be considered methods for desensitizing the nervous system so that it can no longer respond to anaphylactic toxins after its migrainous habit. A full account of such measures has been given by Pagniez.<sup>1</sup> Good results are described from repeated small doses of horse serum and crotonine and from taking peptone on an empty stomach. I have had no experience with these remedies, but judging by the poor results of this line of treatment in epilepsy I am not encouraged to pursue them.

#### *Treatment During Attacks.*

This heading is more comprehensive. A strenuous brain worker cannot go to bed in a darkened room with cold towels round the head and all the other paraphernalia of the luxurious sick-room. If modern medicine can offer nothing better than this to a man whose living depends upon working many hours every day at high pressure then the subject of migraine might well be excluded from practical textbooks. Fortunately the picture is not so gloomy as this, for one of the following two lines of treatment offers a reasonable hope of success. The first is the use of sedative drugs, and of these two are particularly helpful. Phenacetin in the hands of Byrom Bramwell has proved a potent weapon.

He writes:<sup>2</sup>

"I order the patient to take a 20-grain powder of phenacetin as soon as the attack occurs. I tell him, if the first powder does not relieve the headache, to take a second at the end of an hour; and if the second does not cut short the attack to take a third at the end of another hour. I attribute the success which I have had from phenacetin, in a very large number of cases, in which the remedy had been previously given by other practitioners or taken by the patient on his own initiative, to the large doses which I give."

Luminal, as advocated by Wilfred Harris,<sup>3</sup> is also worthy of trial. Not more than  $\frac{3}{4}$  grain three times a day should be taken, and even this dosage may be reduced considerably. Apparently drowsiness is the great objection to the use of this drug.

The second means of attack is the one upon which I wish to lay particular emphasis. For some time I have been using calcium lactate in migraine with success. The only reference to this drug as a cure for headache that I have been able to find in the literature is in a paper by Ross.<sup>4</sup> Here is reported the cure by calcium lactate of cases in which headache is associated with oedema, anaemia, and lowered coagulability of the blood. Among these cases are two of migraine and these also were relieved by this remedy. Calcium lactate is also popularly supposed to cure the morning headache following an evening's gaiety.

The method of administration in migraine is as follows: At the first sign of the approach of an attack, as evidenced by the ocular aura, 30 grains of calcium lactate must be taken immediately; as there must be no delay, the drug must be constantly carried by sufferers, and for this purpose the tablet form is essential. The tablets must be made by a reliable firm and they must be fresh. I have seen instances in which tablets carried in the pocket for some time gave no effect, while the use of a fresh solution, pro-

cured from a chemist near by, gave speedy relief. It must be clearly understood that no claim is made that calcium lactate as given above cures migraine, merely that it aborts the attack and in many cases prevents the appearance of the headache and vomiting and enables the sufferer to continue at work.

#### *Description of Cases.*

##### CASE I.

Medical woman, aged 35. For the last eleven years has been troubled with migraine—very marked visual phenomena, including hemianopsia, severe headache, but no vomiting. Attacks, in spite of many drugs, lasted about two days. Though the onset was usually associated with fatigue and eye-strain and a strong light appeared to precipitate an attack, there was no refractive error. During the last eight years every attack has been aborted by calcium lactate and the headache stage has in no instance been reached. In no attack since calcium treatment was begun has work been interfered with, while formerly in some instances a day, or even two, were spent in bed. Also the attacks have become more and more infrequent.

##### CASE II.

Medical man, aged 28. For many years has had headaches of two distinct kinds—the one is true migraine and the other is apparently due to some alimentary toxæmia. The migrainous attacks since taking calcium lactate have been entirely aborted, whereas the other type of headache is absolutely uninfluenced by the drug.

##### CASE III.

Female clerk, aged 24. For some years has had attacks of vomiting preceded by hemianopsia but no headache. In March, 1921, the patient consulted me for attacks of vomiting which lately had been of daily occurrence; these sometimes were associated with visual auras, but often not. The general condition was naturally very bad and the girl was becoming more and more depressed. Calcium lactate 30 grains was ordered to be taken every night for a few weeks with occasional breaks. The result was quite marvellous: the symptoms disappeared immediately and, owing to the cessation of the attacks, the general health rapidly improved. The doctor reported later that the patient was her old happy self again and quite free from attacks. In this case it would appear that warding off the migraine paroxysms, with their resulting weakening effects, enabled the patient to build up her general condition so that with better health the migraine habit was broken.

##### CASE IV.

Married woman, aged 53. Consulted me in October, 1922, for paroxysmal headaches from which she had suffered all her life. The three stages of typical migraine were experienced. Apparently refractive errors were present, but the correction of these gave no relief. Calcium lactate was ordered, and shortly afterwards her son, himself a medical man, reported that the first attack of migraine was always completely aborted by the treatment, but that a second one often occurred a few days later and then the drug did not give relief. Accordingly luminal,  $\frac{3}{4}$  grain twice daily, was ordered, and this combined with the calcium gave very good results. In August this year her son wrote saying that his mother's attacks formerly kept her in bed two days in every week, now the attacks are much slighter and she is able to get up in a few hours after a paroxysm. "My mother never goes away from home without a full supply of tablets and powder."

##### CASE V.

Married woman, aged 63, first consulted me in September, 1920, for a curious condition of her hands and feet. The appearance was that of a combination of Raynaud's disease and erythromelalgia, and there was acute tenderness added. Though marked arterio-sclerosis was present calcium lactate gave wonderful improvement. In August, 1922, she again consulted me, but this time for typical migraine attacks in which all the stages were represented. Again calcium lactate was successful. There can be little doubt but that the condition of the vessels in this case played a part in the causation of both affections.

##### CASE VI.

Married woman, aged 29; seen in September, 1921. For the last year had suffered from weekly attacks of pain behind the eyes lasting for hours. There was no headache nor vomiting. No errors of refraction were present. A tentative diagnosis of migraine was made and calcium lactate was tried. Two months later the report was "quite cured."

##### CASE VII.

Woman, aged 22 (medical student). When 14 years of age suffered from eye-strain which was relieved by glasses. While reading for the final examination this summer headaches became so bad that even using the eyes for a few minutes for reading was impossible. Oculists were consulted and various remedies tried, but without success. She consulted me as to the advisability of trying calcium lactate. I agreed to this as an experiment. In a précis of her case she reported later, "Calcium lactate grains 30 whenever the headache started was then tried and found to relieve it in about three hours, the effect lasting one and a half to two days." She has now resumed hard work. This patient also suffers from chilblains, but on this condition the drug has no effect.

In neither of the last two cases could a diagnosis of migraine be made and yet the result of treatment was very satisfactory.

been done surgically.

Dr. G. B. BATTER (Dulwich) mentioned his experiences as a general practitioner for thirty-seven years, and stated that the gradual wearing of chronic bronchitis from stuffy rooms and overclothing to fresh air habits and rational clothing had practically prevented cases of habitual chronic bronchitis from occurring. This line of treatment was of more importance even than the undoubtedly valuable treatment by vaccines or surgical procedures in the upper air passages.

Sir THOMAS HORNER (London) said that he had been prepared to expand in greater detail Dr. Perkins's reference to certain general or constitutional factors present in many cases of chronic bronchitis, but Dr. Hyla Groves had done so in some measure. It was a question, he thought, if the infective element had not been stressed too much of late years in this disease. Dr. Inman's experience of vaccine treatment confirmed that idea, and the speaker's experience was very similar. No pains should be spared to assess the nutritive, circulatory, metabolic, and nervous factors in these cases. To rely entirely upon a vaccine, which was not seldom done nowadays, was courtine failure. He would like to raise another question: Was there no such thing as a "mucous diathesis"? Whether the mucous factor were regarded as an expression of a response to subinfection or not was really a quibble; it was certain that this factor differed enormously in different subjects. And the difference was quite likely to depend upon one or more of those general factors already mentioned. He drew an analogy between certain cases of bronchial catarrh and cases of mucous colitis. Not rarely both of these conditions occurred in the same patient. They had dropped the term "bronchial catarrh" of late, and they tended to speak of all cases as "bronchitis." He doubted the wisdom of this change in nomenclature, since he considered that the term "bronchial catarrh" had a definite connotation. There was, he thought, every transition between a true (infective) bronchitis and the bronchial mucous secretion of spasmodic asthma.

Dr. DONALD HALL (Brighton) said that he recalled a discussion on vaccines at the Royal Society of Medicine many years ago, at which it was said it was hopeless to attempt to treat *Bacillus coli* infections or chronic bronchitis with vaccine. In his own practice he had found autogenous vaccine of value in chronic bronchitis, and had had a very mixed experience of the results of operative treatment of the upper respiratory tract.

Dr. J. J. PERKINS, in reply, said that he was satisfied on the whole with the result of the discussion. Speakers appeared to regard chronic bronchitis in the main as a secondary or symptomatic condition. All were agreed on the importance of educating people to an open-air life in any part of this country, to the necessity for removing underlying conditions, and to building up the patient.

## THE RELATIONSHIP BETWEEN ATMOSPHERIC ELECTRICITY AND EPILEPTIC FITS.

(Abstract.)

Mr. GEORGE ALMOND (Bournemouth) displayed some charts showing the relation between variations in atmospheric electricity and the incidence of its among epileptics.

Dr. Tylor Fox, of Lingfield Epileptic Colony, had furnished him with the details of its occurring daily among the patients for two years. A chart showed these for the whole of 1921. On the same chart was the daily range of atmospheric potential. It was seen that there was a similarity, especially a seasonal one. In the spring and autumn both fits and potential were generally above the mean for the year; and in the summer months both were well below the average. Mr. Almond thought it might be expected that when the electric condition was high fits might be more numerous; but many would think that an epileptic

that other meteorological factors might show a reverse.

Continuous line = epileptic fits. Broken line = atmospheric electricity. Dotted line = temperature (curve inverted). figures = months (1920-21).

took temperature; the fits might vary inversely but not so close as when compared with the monthly temperature. There was some correspondence. The depression was more steady in summer months, and the lowest point of its was lowest point of temperature, which were in different years; whereas with the potential they were identical months. He thought the interdependence was not only in regard to epilepsy, but towards nervous manifestations—for example, asthma, neuritis, psychoneuroses, etc. It enhanced the value of the logical factor, and he regretted the inadequacy of observation in this respect. There was only one station for electrical variations in England and one in Scotland (at Eskdalemuir).

## OBSERVATIONS ON THE LIFE-HISTORY AND BIOLOGICS OF PHLEBOTOMUS PAPATASII.\*

WING COMMANDER HAROLD E. WHITTINGTON M.B., CH.B., GLAS., D.P.H., D.T.M. AND H.LOND AND FLIGHT LIEUTENANT ALAN F. ROOK, M.R.C.P. LOND., D.P.H. CAMB., ROYAL AIR FORCE MEDICAL SERVICE.

(Members of the R.A.F. Sandfly Fever Commission.) (Abstract.)

PREVIOUSLY it was not understood how the phlebotomus fever was carried over the winter in the imagines of the phlebotomus do not live through the winter, and as Doerr and Britz claimed to have seen the blood of man only contains the virus during forty-eight hours of the fever. This latter point, otherwise how are relapses to be explained? These observations form part of the researches carried out by the R.A.F. Sandfly Fever Commission, during the years 1921 and 1922. The Commission consisted of: in 1921, Squadron Leader R. Whittington, Corporal G. H. Noakes, and Aircraftman R. Whittington, Squadron Leader H. E. Whittington, Flight Lieutenant H. E. Whittington, and Aircraftman R. Whittington, in 1922, Squadron Leader H. E. Whittington, Flight Lieutenant H. E. Whittington, and Aircraftman R. Whittington, in 1923, Squadron Leader H. E. Whittington, Flight Lieutenant H. E. Whittington, and Aircraftman R. Whittington.

## CASE VIII.

Medical man, aged 33. Occasional attacks of migraines for some years with marked visual phenomena and headache but no vomiting. In 1922 there were five attacks within a short period and in four of these absolute and immediate relief was obtained after taking calcium lactate. In the fifth attack no supply of the drug could be obtained and the consequent headache lasted for more than twenty-four hours. After this an error of refraction was corrected and the attacks ceased.

## CASE IX.

Medical man, aged 26. Typical migraine attacks unaccompanied by vomiting since February, 1925. I ordered calcium lactate in the usual dose. He reports (October, 1923) that he has experienced eighteen attacks, of which fifteen were aborted by the treatment and no headache resulted. In two of the remaining three attacks no calcium lactate was taken and in the third the dose was taken too late, with the result that headache followed in each instance.

## CASE X.

For notes of this case I am indebted to Dr. E. I. Claxton of Bootle. Woman, aged 47. This patient had had recurrent headaches, showing all the typical events of the migraine syndrome, since she was 7 years of age. At first the attacks were at monthly intervals, but since reaching the age of 30 they have become more frequent. In November, 1922, luminal was exhibited, but this drug, even in small and widely separated doses, made the patient so drowsy that its use had to be discontinued. Speaking of this patient the doctor wrote in a letter received in September of this year: "After hearing your note read at the Liverpool Medical Institution on January 4th, 1923, I put her on a 30-grain dose of calcium lactate, which must be taken within half an hour of the appearance of the visual symptoms. This time the attack; the only time it failed was when she neglected taking the dose within the prescribed half-hour." He adds: "I feel convinced that this drug is the only one that has given relief to a patient who has been a life-long sufferer from migraine." It is only fair to add that in a verbal communication Dr. Claxton has since informed me that quite recently the patient has vomited on one or two occasions.

Dr. J. Flanagan of Bootle reports that he has tried my method of treatment in three typical migraine cases occurring in women during the last nine months. The attacks were aborted in all.

No object is to be gained by multiplying such examples; suffice it to say that, in my series of 20, 16 patients stated that their attacks have been aborted by the calcium lactate treatment. Of the remaining 4, 2 were apparently cured by general remedies and consequently had no need to try calcium, and 2 experienced no relief. Of these two apparent failures one is a medical man whose case is complicated by a gunshot wound of the skull, and in his attacks he experiences great pain in the region of the scar; the other is the wife of a friend whom I have only treated by proxy, and possibly she may not be suffering from true migraine at all.

It is not right that definite conclusions should be drawn from such a small series of cases. Nevertheless, I have taken the opportunity of publishing my results in order that this treatment may be tried on a wider scale and its efficiency proved.

## THE NATURE AND TREATMENT OF SPRUE.\*

BY

H. H. SCOTT, M.D., M.R.C.P. LOND., D.P.H.,  
D.T.M. AND H. CAMPB., F.R.S. EDIN.,

ASSISTANT IN HELMINTHOLOGY, LONDON SCHOOL OF TROPICAL MEDICINE.

Various theories of the causation and modes of treatment of sprue have been advanced, but hitherto treatment has been almost entirely empirical. The method I wish to bring forward has at least the merit of a rational basis. The best way in which I can briefly place before you the line of reasoning on which the theory first originated is to relate the history of a patient a consideration of whose symptoms and progress formed the basis of the theory.

The patient in question contracted the disease in China in 1920. The usual symptoms were present: the loss of weight was rapid, sometimes 3 lb. in a week, and the mouth symptoms were very severe. On more than one occasion there were over thirty aphthae in the mouth, so that the taking even of milk was painful. These spots are spoken of as aphthae, but they differ from what we usually recognize under this term. After a bout of "acidity"—burning pain

in the stomach with acid rising into the oesophagus—there would ensue in twenty-four hours or so a crop of four or five very tender spots on the tongue, the frænum, or the level of the second molar, or on the gums and cheek. There was nothing visible at this early stage, but in a few hours small red patches would develop which in another twenty-four to thirty-six hours would break through or become abraded and intensely painful little ulcers would appear.

Another symptom not mentioned in the books, but very marked in this case, and in many others whom I have questioned, was cramps, or rather carpo-pedal spasms. Tetany is spoken of, but the former is, in my opinion, much more common. During the night the patient frequently had to spring out of bed and pace the floor to relieve these cramps of the legs and feet; when writing, cramps of the hands would come on, so that the penning of more than a brief letter became impossible.

He suffered many things of many physicians. He took nearly all the yellow santonin there was in the colony; he was given autogenous vaccines (*Streptococcus salivarius* and others), emetine injections, was dieted with milk at one time, with the Salisbury method at another, with a diabolical preparation to which sprue itself is, in my opinion, preferable—namely, liver soup—at a third. Finally, he was sent on a voyage to Canada with the idea that a "spell of cold weather would drive out the sprue."

After some months, during which he became progressively worse, he managed to crawl with aid on to a vessel for England, and arrived in March, 1922. He was taken into hospital the following day, fortunately under the care of one who had for years been studying the disease both at home and in its endemic centres abroad. Confinement to bed and a milk diet for some weeks led to considerable improvement, and the patient went to the country to convalesce. Any attempt, however, at passing on to even decent invalid food led to more sore mouth, more flatulence, acidity, large stools, loss of weight—in fact, to a return of the typical symptoms. Two relapses occurred during the ensuing nine months, and the patient was invalidated from the service in consequence. At each of the relapses the cramps returned as badly as ever.

I now began to ponder whether it was not possible to trace to some common origin these various symptoms. Dyspepsia and large pale, pasty motions are amongst the earliest manifestations. The stools show a relative excess of fatty acids and a relatively large excretion of calcium. The urine also in some cases contains more calcium than normal. The flatulence, acidity and diarrhoea, the aphthae, languor, and loss of weight, might all arise from states of intestinal intoxication. Next came to mind the peculiar association of carpo-pedal spasms with calcium deficiency, the correlation possibly of these with the diarrhoea and intestinal toxins, referring them to the group of organs which have been credited with the control of both these conditions—the parathyroids. These are believed to have a twofold function—namely, the regulation of calcium metabolism and of detoxication, in particular of the poisons of intestinal origin. In addition to this, but as subsidiary and not acting in all cases, is the condition of hyperchlorhydria. If this is present we may have as a result an excessive production of secretin by the action of the acid of the gastric juice upon the prosecretin of the mucous membrane of the duodenum. Excess of secretin leads to stimulation of the pancreas with an increased splitting up of fats, so that the normal ratio of neutral fats to fatty acids is diminished, as I have detailed in a former paper. This, however, is but a side issue, and does not come into play in all cases, for in sprue the gastric contents may show hyperchlorhydria, normal acidity, or hypochlorhydria.

Here was enough to start on. Examination of the blood revealed the fact that the total calcium was little, if at all, diminished, except in later stages or in very severe cases, nor was the coagulation time prolonged. The inference, therefore, was that in spite of the loss of calcium in the excreta sufficient was being absorbed to maintain the normal total calcium in the blood.

Calcium, according to the researches of Vines and Grove, is present in the blood in two forms—the ionic or free, and the combined or coagulative. Seeing that the latter was

\* Read at a meeting of the Section of Tropical Medicine and Parasitology of the Royal Society of Medicine (see page 1157).

not deficient, although the symptoms pointed to calcium deficiency, it was inferred that the ratio between the two might possibly be upset. In the blood plasma there is normally between 10 and 11 mg. of calcium per 100 c.cm., of which 6.5 mg. or thereabouts is in the ionic state and the remainder combined. This latter fraction is concerned with the process of coagulation, and during the clotting this 4 mg. of "combined" calcium becomes changed to free calcium, due to the breaking down of a calcium-lipoid complex. In normal persons the whole of the 10 mg. should, after the blood has clotted, be in the free state in the serum—that is, there should be no residual combined calcium. In conditions of so-called "calcium deficiency" the blood after clotting is found still to contain some calcium in the combined form, and there is thus a relative deficiency of ionized calcium.

Calcium in the form of the lactate was then prescribed for the patient and the symptoms improved, but though the drug was continued relapse took place. Further increase of the calcium led again to improvement, followed again by relapse. Perhaps the augmented intake brought the ionic calcium temporarily to the normal, and the relapse would then be explainable by the ratio again becoming, or still remaining, disarranged. The amount of the calcium was then reduced and parathyroid extract was given. I am not sure now whether the former drug need be given at all, since the food as a rule contains sufficient calcium for the needs of the body. A wonderful change took place. Developed aphthae rapidly healed, commencing ones, as *soro papillae* and tender spots, receded without becoming aphthae, the flatulence was diminished, the stools became fewer and smaller, the colour began to return, and the general sense of well-being was regained. Within so short a time as a fortnight all the more acute symptoms had disappeared; food was increased, calcium was stopped, and in five weeks the patient was on ordinary diet. The parathyroid was gradually left off, and in six weeks from its first employment was stopped altogether. Nearly eleven months have gone by and he has lived a normal life, working hard Sundays and weekdays, paying no regard to diet, taking alcohol on occasion, and has not had a day's illness since.

This is not altogether an exceptional case. I have records of other patients who have done nearly, some quite, as well; one even better.

Let me now briefly review the symptoms associated with calcium deficiency, or, as it is preferable to call it, irregularity of calcium metabolism, and see how they apply to the disease we are discussing.

When the European goes to the East—for instance, to India—he continues to indulge his preference for a meat diet and partakes also of some of the native dishes, such as curries and highly seasoned rice. His thirst is slaked by iced drinks, often sweetened, and sometimes containing a considerable quantity of alcohol. His diet there is thus in several ways unnatural, and hyperchlorhydria is common. The effect of this I have already mentioned elsewhere.<sup>1</sup> Gastric and intestinal disturbances are commonly associated with stomatitis and aphthae. The excess of acids in the food also plays a notable part in sprue; the saliva itself is, in many cases, acid.

In other countries where sprue is endemic—China and Porto Rico for example, to instance places in the Far East and in the West—the food and the methods of cooking lead to an increased ingestion of fats. Koelmann and Petzsch by adding fats to the diet of healthy dogs showed that a considerable loss of calcium occurred, while Rothberg and others noticed that in children to whom an excess of fats was given the retention of calcium was reduced. This they explained by the increased formation of calcium soaps in the intestine, unabsorbed fatty acids being eliminated in the stools as soaps of potassium, sodium, and calcium, leading thereby to the impoverishment of the body in respect of bases. Again, Korenchevsky found that in animals on a diet deficient in calcium diarrhoea was noticed, together with such symptoms as loss of weight and increased nervous excitability.

How far vitamin action comes into play I do not venture

to say, though, according to Aulde, a lack of calcium when vitamins are supplied induces the same changes in the endocrine glands as are seen in conditions where calcium in the diet is abundant but the vitamins are deficient. In other words, vitamins are unable to fulfil their function in the absence of inorganic salts.

In calcium starvation (accompanied by deficiency of fat-soluble factors in the diet) there is a considerable loss of calcium and phosphorus from the organism. Korenchevsky found in his experiments that administration of calcium salts under these conditions led to a temporary improvement in the balance of calcium, but as soon as the extra intake ceased the retained calcium was soon excreted. Before I came across the account of Korenchevsky's work I had stated that this was what probably occurred in sprue. The taking of calcium led to improvement of symptoms, but the dose had to be increased because, so I inferred, it was being improperly regulated. If we think for a moment of the nutrients recommended for sprue—certain fruits, milk, carrots, young spinach, potatoes—we see that all are characterized by an excess of bases and a richness in calcium.

The amount of calcium in the blood does not depend solely, or even in the main, upon the amount of calcium salts taken in the food or as medicine, but on the efficiency of the calcium-regulating mechanism—the parathyroids with their twofold function of detoxication and regulation of calcium metabolism. The mechanism of this regulation would naturally be upset if the toxins were more than could be dealt with, and the absorption of certain toxins appears to lead to such disturbance; the ionic calcium suffers diminution and becomes relatively deficient first, while in the later stages there is an absolute deficiency. Calcium deficiency is therefore regarded as an indication of toxin absorption.

In cases of sprue, then, we have one of two conditions. In the one where fats are in excess we have an excessive excretion of calcium in addition to intoxication of intestinal origin; in the other protein excess with intestinal toxin formation. In both, the parathyroid detoxicating function is overburdened, with a resultant disorganization of its calcium-regulating function, while there may be in addition diminished calcium absorption. Both functions, therefore, of these glands are interfered with.

A few figures of the calcium content of the blood of a normal person and of patients suffering from sprue are given in the table. The specimens were sent to Dr. H. W. C. Vines, of the Cambridge Medical Schools, Fellow of Christ's College, who very kindly undertook to examine with regard to their calcium content specimens of blood sent up. He was not told the histories of the cases when the specimens were sent, and I think it will be agreed that the results obtained afford remarkable corroboration of the theory I have brought forward.

Table of Calcium Contents of Blood Normal and in Cases of Sprue.

	Free Ca.	Combined Ca.	Total in mg. per 100 c.cm. serum.
Normal (after clotting) ... ..	10.7	0.0	10.7
McG. Fairly severe case.			
Before starting treatment ... ..	6.1	3.8	9.9
After one week ... ..	8.1	1.8	9.9
After two weeks (good progress) ...	10.1	0.0	10.1
H. S. Average case. Not taken on arrival. Weight 118 lb.			
After one week (gained 3½ lb.) ...	7.0	2.9	9.9
After two weeks (weight 127 lb.) ...	7.4	2.7	10.1
After three weeks (weight 133½ lb.) ...	10.8	0.0	10.8
After four weeks (weight 142½ lb.) ...	10.8	0.0	10.8
C. W. Mild case; nine months ill. (Bombay.)			
Before starting treatment ... ..	8.0	1.9	9.9
After two weeks (to have fish, chicken, potatoes, milk, biscuits, carrots, eggs)	8.9	1.2	10.1
After three weeks (to have meat, beef, mutton, ordinary food. After four weeks, reported himself quite well, 2½ lb. above normal weight.)	10.4	0.0	10.4

It will be seen that in a case of somewhat severe sprue before commencing treatment there was a reduction of

Characters which remain constant throughout

for the insects to feed voraciously on organic soft earth. Frequently in the search for food on top of the insect is the chitinous remnant of a thin film of water caused by their hiding place and coming into contact with the insect's sensitive sense organs. The insect passes the winter months in the form of a pupa in length of 3.78 mm. In the last day of its original size—that is, from 0.46 mm times its original size—and in that time it has six days of its life. The average length of the pupal development, during which there is no change in development, is 1 mm. In the description of the insect, we should note that it is not a very common insect, but it is not rare in the mountains of the Caucasus.

(Note.—Each larva was kept in a separate Petri capsule, and it was noted that those larvae which possessed coiled caudal bristles after moulting showed the same characteristics in future moultings, and on the emergence of the imago the sex was undoubtedly made in the three cases under observation. Too few observations were made to establish, or otherwise, any relation between the characters of the caudal bristles and the sex.)

When the creature is fully ready to moult, usually on the seventh day of larval life, the body markings are indistinct and the body hairs appear blurred and duplicated, like outlines in a negative which has been slightly overexposed. This appearance is due to a separation of a portion of the chitinous head from the rest of the larval skin, by means of which some air enters between the skin to be cast and the new skin. The new body hairs lie between the two skins; the skin to be cast is so delicate that the hairs can be seen through it. At this stage the larva becomes more active and mounds the ground with its head—the portion of the head to strike the ground being in the region of the mouth. The chitinous head-cover becomes loose and puffs out as the head always from side to side. Eventually, one relatively severe tap causes the chitinous covering of the head to roll off like a sack, and be held up to the head to roll off like a sack, and be held up to the head to roll off like a sack. The larval skin takes place on the dorsal surface at the junction of the head and body. With the removal of the head-covering, the head of the emerging second-stage larva is displayed. The head is pearly white, except for the brown. Gradually the larva withdraws itself from the old skin; the caudal bristles and ventral body hairs help to anchor the old skin to the surface on which it is lying. The larva emerges gradually, with its head against the ground. In some cases the head-covering is completely separated from the rest of the shed larval skin, the two being some little distance apart. The ventral bristles as the average time taken for the complete emergence of the larva after the head-cover has separated. The last portion to emerge is naturally the caudal bristles, and during the moult they can be detected throughout the shedding skin. Not only are these bristles present at the time of moulting, but they are black and have attained their maximum length for the second instar at larval life. There are now four bristles, arranged in two pairs, the outer pair being about two-thirds the length of the inner pair. In some instances the caudal bristles are straight when the creature emerges from the cast; in others they are coiled round the posterior extremity of the body in the fashion of a pigtail. In the latter case the bristles straighten out during the next two to three days.

*The Second Instar.*

*The Second Instar.* (Plate I, Fig. 8.)

(\*) Note.—Each larva was kept in a separate Petri capsule, and it was noted that those larvae which possessed coiled caudal bristles after moulting showed the same characteristics in future moults, and on the emergence of the imago the sex was undoubtedly male in the three cases under observation. Too few observations were made to establish, or otherwise, any relationship between the characters of the caudal bristles and the sex.)

are arranged in two pairs, the outer pair being about two-thirds the length of the inner pair. In some cases the caudal bristles are straight when the animal is in the cast; in others they are arched in the fashion of a pistol. In the latter case the bristles straighten out during the next two to three days.

of the body, and levering with its head against the ground. In black-chinned sparrow-heads, the larva remains intact with the head-covering is completely separated from the rest of the shed larval skin, the two being some little distance apart. The average length is the average taken for the complete emergence of the larva after the head-cover has separated. The last portion to emerge is naturally the caudal portion, and during the moult it can be detected through the shedding skin. Not only are these bristles present at the time of moulting, but they are black and have attained their maximum length for the second instar of larval life. There is a maximum length for the second instar of larval life. They are black and have attained their maximum length for the second instar of larval life.

The larvae are yellowish-brown, with a darker brown line running down the middle of the back. The head is brown, and the legs are yellowish-brown. The pupa is brown, and the adult is brown. The caterpillar is found on the leaves of the plant, and the pupa is found in the soil. The adult is found on the leaves of the plant.

[illegible][illegible]

Population.

The duration of time between the hatching of pupation may be as short as twenty-four days. The latter figure refers to hibernation in the fourth larval stage. The larva gradually empties its gut before pupation. An excess of moisture or

ture below 65° F. retards pupation. When the larva seeks a drier spot—the under surface of a leaf, for example—the surface of the puparium becomes very sluggish. It may lie with its head raised like a cobra preparing to strike. The puparium is distinctly bloated, dull, wax-like, and semi-transparent. The surface of the puparium is an ideal situation for the deposition of eggs. The eggs are laid against the surface of the puparium.

the pupa, in nature, usually occurs at night. The act of the pupa like a wrinkled stocking. The act of the pupa is to come up and collect around the three ventral segments. The cast-off larval segments are expelled backwards of the body and by writhing through this rupture the pupa gradually separates on the dorsum from the head and anterior portion of the body, the head and anterior segments slow arching in. Eventually, after numerous slow arching movements, the third segment separates from the rest, the third segment being more than the rest, the third segment being the most anterior body segments of the larva. During the twenty-four hours preceding the pupation, the head again it raps its head against the ground and again it raps its head against the ground.

more than one-third in the ionic calcium, though the total was very little reduced. In all, as they progressed, this figure went up, almost *pari passu*, and when the free calcium reached normal and there was no residual combined calcium the patients expressed themselves as feeling well and very hungry, and there were no untoward symptoms.

In my previous paper records were given of individual cases and also an explanation, or possible explanation, of the rationale of the modes of treatment in vogue. There is no need to repeat these, but as Sir Leonard Rogers believes so strongly in the efficacy of vaccines in this disease and has reported many good results, I may perhaps be allowed to say a word or two on that head, as it bears on my own theory. According to what I have advanced the detoxicating function of the parathyroids becomes overtaxed: it has been working overtime, as it were, for probably a considerable period, and has finally had to succumb or at least take a temporary rest. The organism cultured from the mouth or stool is only one of several which may have had a hand in the toxin production, and the effect of the vaccine would be to render one of the *foes hors de combat* and reduce the inimical influences to such an extent that the parathyroids can now cope with them, especially when the treatment is combined with mental and bodily rest in bed and an addition of calcium by a diet consisting largely of milk. This explains, I think, the good results obtained from so many different vaccines, provided they are autogenous.

"There are twenty different ways  
Of writing tribal lays,  
And every single one of them is right,"

says Rudyard Kipling. It may be the same in sprue. Twenty different men might find twenty different organisms, make vaccines from them, and report good results in each case, for they might each have hit off an organism responsible, in part at least, for the toxin produced in each individual patient, and by combating it relieve the over-worked parathyroid and enable this gland to take up its duties again. But no single vaccine would prove effectual in all cases, and we may thus explain the individual good results of streptococci in some of Sir Leonard Rogers's patients, of monilia in Ashford's, of coliform bacilli in various others.

Another form of treatment, highly commended by some

in the Far East, is powdered crabs' eyes and cuttle-fish shell. I do not know the chemical composition of the former, but the latter contains much calcium. Another favourite medicine is *pulvis Bataviae* co. What is this but concentrated calcium?

It has already been stated that the foods found best for sprue patients contain quantities of this base. In a word, the best diet and the most successful drugs hitherto used have supplied abundant calcium, a base which serum analyses have shown to be deficient—sometimes absolutely, more often relatively—without exception in those tested so far. The constituent parts are ill balanced, and the disease, therefore, calls imperatively, not so much for a more abundant supply of calcium as for support in regulating its disposal—that is, for parathyroid. The rest in bed, which is important in the early stage of treatment, puts the whole system under the best conditions for recovery of function.

When I wrote the last communication on this subject I could only speak of patients treated in England, but I stated that it would be of interest to know whether such felicitous results could be obtained abroad as I had had here with cases which, by the great kindness of the physicians to the Hospital for Tropical Diseases, I had been permitted to see in addition to those whom I myself had treated outside. I have since had reported to me the cases of eight patients in the Far East all of whom had been under the usual methods of treatment for one and a half years or more. One had come to this country for treatment, and, having been kept for a long time in hospital, had been obliged to return. He was assured that he would not live through the voyage, and, in fact, was carried ashore on a stretcher. He started the calcium and parathyroid treatment: in three weeks was up and about, and in five was carrying on his business.

If such fortunate results can be obtained in countries where the disease is endemic (and in most of these its prevalence appears to be increasing), much sickness and invaliding will be avoided and not a few deaths prevented, a marked contrast to what obtains at present—a miserable voyage home on ship's food, a stay of several months in hospital on the diet of a toothless infant, followed by months of food restriction, an ever-present haunting dread of a recurrence of symptoms, and a veto on any idea of a return to a tropical climate; in other words, the ruin of many a young man's career.

## British Medical Association.

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, 1923.

#### SECTION OF MEDICINE.

Sir THOMAS J. HORDER, Bt., M.D., F.R.C.P., President.

#### DISCUSSION ON CHRONIC BRONCHITIS.

I.—JOSEPH JOHN PERKINS, M.A., M.B.CAMB., F.R.C.P.LOND.,

Consulting Physician, St. Thomas's Hospital.

THE subject before us this morning, which may seem a very simple one, was chosen in deference to the feelings expressed by Branches that bronchitis was well worth discussion, on account of the frequency of the cases in practice and the high death roll that follows—the Registrar-General's figures for 1920 were 1,010 deaths per million living.

The Branches felt that little advance had been made in treatment, except perhaps that with some men a routine use of vaccines has taken the place of a routine giving of expectorants, and they hoped that a comparison of counsels which Sophocles has said is characteristic of the wise, might lead to improvement in treatment and even might help towards prevention also.

The Committee agreed and accepted the suggestion, but decided that the time at our disposal would not admit of

a discussion of the whole subject, including acute bronchitis and pulmonary lesions consequent on bronchitis. They therefore limited the subject to recurrent and chronic catarrh of the trachea and bronchi.

I shall be brief in my opening remarks, and will first outline the ground which will be covered this morning.

Catarrh, one may say, is immediately due to invasion by infecting organisms. Dr. Inman and others will deal with the bacteriological aspect of the subject and the value to be placed on vaccines. But we may go deeper than the question of immediate treatment, and consider the possibility of prevention. Preventive antiscarrhal inoculation is a method largely used, of the value of which many members hold a high opinion. This, we hope, will come into the discussion this morning, and we expect to get some solid information from their experience.

Further, are there not conditions which predispose in individual cases to recurrent bronchitis and invasion by micro-organisms? If such can be found and dealt with treatment and prevention will be placed on a sounder footing. In other words, to use the well known simile, the soil should be borne in mind as well as the seed.

Predisposing conditions would seem to fall under the following heads: (1) The part played by occupations and trades; on this Professor Collis has sent in a short statement in which he emphasizes the importance of "atmospheric pollution" in the causation of bronchitis. His paper, with full statistics, will appear in print shortly. (2) The part played by climate in causation and treatment. (3) How far are pre-existing local pathological conditions present, especially in the upper respiratory tract, in these patients, with the result that they carry in themselves a

PLATE I.

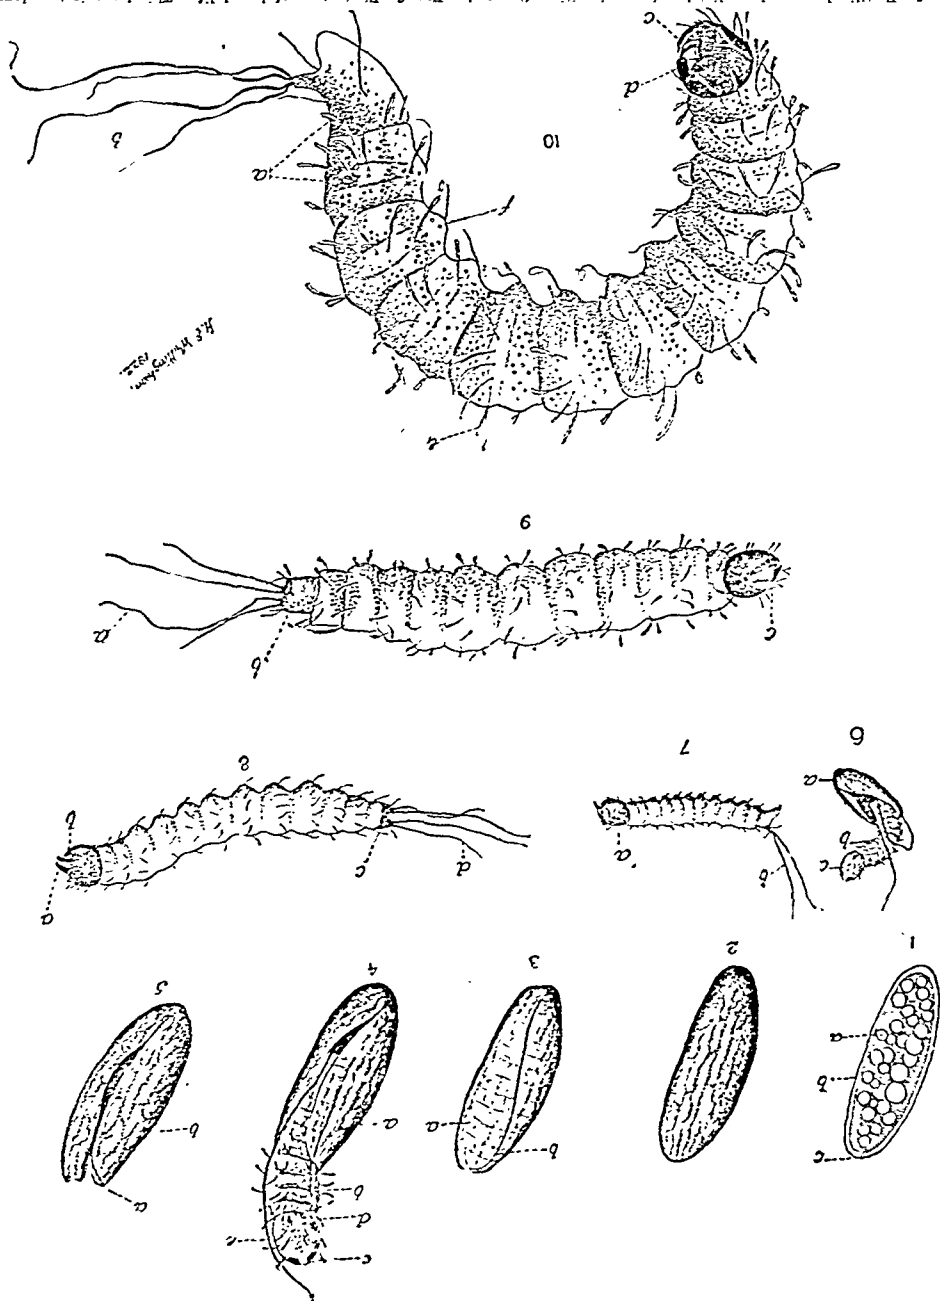

FIG. 1.—Fertilized ovum immediately after oviposition (transmitted light). *a*, Fat globules; *b*, egg-shell; *c*, micropyle through which sperm gains entrance to fertilize the ovum.

FIG. 2.—Fertilized ovum seven days after oviposition. Note the flattened (ventral) surface, and the convex (dorsal) surface, also the striations or scutellations of the egg-shell.

FIG. 3.—Fertilized ovum nine days after oviposition. *a*, Segmentation of embryo; *b*, caudal bristles seen shining through the thin divided egg-shell. Some of the surface striations of the shell are obliterated by the dissection.

FIG. 4.—Fertilized ovum nine days after oviposition. *a*, Hatched egg-shell; *b*, larva in the process of emerging; *c*, mandibles; *d*, egg-tooth; *e*, caudal bristles. The emerging larva is faint white except for the brown pigmentation of mandibles, labial plate, and egg-tooth, and the black caudal bristles.

FIG. 5.—Hatched and emptied egg-shell of *Phlebotomus papatasi*. The larva has completely emerged. *a*, Rupture of shell extending from anterior almost to posterior pole; *b*, rupture of shell extending from anterior almost to posterior pole; *c*, ruptures of shell extending from anterior almost to posterior pole.

FIG. 6.—Larva emerging from egg-shell. *a*, Shell; *b*, larva; *c*, head of larva. The larva is dotted with brown pigmentation.

FIG. 7.—Larva emerging from egg-shell. *a*, Shell; *b*, larva; *c*, head of larva. The larva is dotted with brown pigmentation.

FIG. 8.—Larva emerging from egg-shell. *a*, Shell; *b*, larva; *c*, head of larva. The larva is dotted with brown pigmentation.

FIG. 9.—Larva emerging from egg-shell. *a*, Shell; *b*, larva; *c*, head of larva. The larva is dotted with brown pigmentation.

FIG. 10.—Larva emerging from egg-shell. *a*, Shell; *b*, larva; *c*, head of larva. The larva is dotted with brown pigmentation.

FIG. 7.—First stage of larval life. This larva is two days old. *a*, Black head showing Y-shaped mark and egg-tooth within Y-shaped mark; *b*, single pair of caudal bristles. Note the twelve body segments.

FIG. 8.—Second stage of larval life. This larva is seven days old; the first moult had taken place the previous day. *a*, Mandibles; *b*, labial plate; *c*, pigmentation of dorsum of distal end of last abdominal segment; *d*, two pairs of caudal bristles.

FIG. 9.—Third stage of larval life. This larva is thirteen days old; the second moult had taken place on the tenth day. In this stage there are two pairs of caudal bristles (*d*), and pigmentation of the whole dorsum of last segment of body (*b*). This is a dorsal view of the larva. The minute antennae (*c*) are seen just in front of the Y-shaped mark.

FIG. 10.—Fourth and last stage of larval life. This larva is twenty-two days old and is shown in a typical attitude adopted for a few days prior to passing into the pupal stage. In this stage there is pigmentation of the dorsum of the penultimate and last segments of the body (*b*), and two pairs of large caudal bristles (*d*). Note mandibles (*a*) and egg-tooth (*c*).

constant reservoir of micro-organisms ready to infect the bronchi by aspiration? These are local predisposing conditions in the nose and pharynx, but (4) Are there no general constitutional factors in these patients, which prepare the way for infection, and which well considered treatment could seek out and remove? Before the morning is over I feel that we shall have reason to see that these suggestions are well founded, that in a large number of the cases of chronic and recurrent bronchial catarrh such predisposing conditions, atmospheric or personal, and in the latter local or general, are certainly present and that they are the key to the position, too often overlooked or perhaps not sought.

For myself, I draw a distinction between chronic or recurrent bronchial catarrh and a single acute attack of bronchitis. A single acute attack, it seems to me, may occur in anyone without special predisposing conditions; it is a matter of opportunity, the result of a sufficiently virulent microbial infection which the patient chances to encounter, and which may overcome even a stout resistance. For the single acute attack I find the ordinary drugs very useful and vaccines so valuable as to be truly curative. But when catarrh recurs frequently or becomes chronic and constant, vaccines, I find, are more efficacious in relieving symptoms, such as cough or spasm, in which they are undoubtedly very useful, than in curing. In fact, as the sceptic puts it, in chronic bronchitis as you chase out one microbe another takes its place. In such chronic cases my experience leads me to look for a pre-existing or underlying predisposing condition, and I believe one can be found in a surprising proportion of cases; on the treatment of this underlying condition success depends.

Among the predisposing conditions none is so common, in my experience—and I wish this to be my particular contribution to this morning's discussion—as some chronic diseased condition of the upper respiratory tract—mouth, tonsils, pharynx, nose—a local reservoir of microbes, as I said before, from which infection of the bronchi by inhalation can easily take place. Unless this focus of infection is dealt with, other treatment, including vaccines, is futile.

Bad pyorrhoea, unhealthy tonsils, a foul pharynx, nasal disease or trouble of all kinds, whether mechanically obstructive or infective only—these are the lesions I find so frequent, and believe to lie at the root of so many cases of chronic or recurrent bronchitis, and the treatment of which I find to be so effective in preventing the bronchial catarrh. I allow this is well enough known in a general way, but it is not sufficiently realized or acted on in practice. The frequency with which in childhood adenoids predispose to bronchitis is a truism, but similar conditions, such as those just named, are true for the adult. The nose and pharynx should never be overlooked. It is unnecessary for me to pursue the matter in detail, as Mr. Seecombe Hett will deal with it later.

To touch on other predisposing factors which require attention, if treatment of chronic bronchitis is to be effective, in many cases metabolic conditions are the key. Here I place obesity, whether its effects be toxic or mechanical, overfeeding (the so-called gouty bronchitis), and alcoholic excess. For these patients self-denial in food and drink and reduction in weight (by graduated exercise, massage, the Turkish bath, and spa treatment), a reduction of the intake and an increase of the output, to promote elimination and restore mobility to the chest, are necessary.

I wish, then, to urge the importance of such predisposing conditions as I have named, local and general, especially the local, in the causation of recurrent attacks of bronchial catarrh. Neglect of these factors I respectfully suggest is one of our two main failings in dealing with recurrent bronchitis. Our other fault, I believe, is our failure to continue our efforts until a really satisfactory convalescence is secured. We are too apt, as soon as an attack has subsided, to rest on our oars and think that everything necessary has been done, whereas we should still press on until we secure a return to the former active life.

I refer here to the importance of the preservation or restoration of the open-air habit of life, and the value of respiratory exercises. Fresh, pure air is of value not only

for the consumptive. In chronic bronchitis, as Professor Collis will tell us, contaminated impure air is the enemy, not chills and exposure. It has been well said that no one ever "catches cold" while deer-stalking in the Highlands—only on return home.

The bronchitic should cling to the open-air life or habit as long as possible, and postpone as late as possible the evil day when he is shut up in the hot stuffy rooms to which he is too prone—the beginning of the end. A change to a milder climate, after being laid up indoors, is, of course, a useful stepping stone to the resumption of ordinary life; and a good general plan for the bronchitic is to take the usual annual holiday in the winter, securing a change to some place where outdoor exercise is freely possible and pleasant. Such a break helps many a patient to get through the winter without an attack, and, reinforced by the following summer, puts him in a strong position to face the dangers of the coming winter.

With such simple precautions the bronchitic can be kept in fair working condition for several years. Ultimately, in the later stages of the malady, permanent residence in a warm climate may possibly become a necessity, but that should be reserved for the later stages. A bracing climate should be adhered to as long as possible, and that climate is sufficiently warm which allows of daily open-air exercise. The climate of the Alps, pure dry cold, has long been known to be of great benefit in the earlier stages of the complaint, and many a bronchitic does not fear cold provided the air is dry. On this point I cannot do better than quote a letter received from an old medical friend, now well in the seventies, who suffers much from catarrh in London. He writes: "I am wonderfully well. I went off on May 10th to stay with a friend on the Welsh moors, 1,500 feet above the sea; heard on my arrival that they had had four inches of snow round the Lodge that morning. I arrived in a snowstorm; we had gales and blizzards every day till May 21st, then gales and hail. We often found the ground white in the morning, but we got some gleams of sun. I was out all day, and four days we went into the valley to fish. In spite of the weather I felt as fit as possible and lost my cough almost entirely. Nothing like fresh air."

It is often impossible, I know, to alter a man's occupation or get him an expensive climatic change, but we can improve the conditions of his life in office and home; we can do away with the heated atmosphere, which acts as an incubator for microbes. The atmospheric pollution which, you will hear later, Professor Collis finds to be the main source of bronchitis, does not apply only to "trade dust." We can keep up the practice of outdoor exercise and encourage the hardy habit of body which defies chills.

Finally, a valuable adjunct in the treatment of the bronchitic is to be found in respiratory exercises, such, for example, as have been successfully systematized by Mr. Cortlandt MacMahon of St. Bartholomew's Hospital. In most people the lower portions of the lungs are habitually hardly used, and the object of such exercises is to restore and even increase the movement of the lungs. They carry with them also the improvement in oxygenation and circulation which follows increased activity. Training in singing has often, in earlier life, the same effect in banishing a catarrhal tendency.

Briefly, MacMahon's system is divided into two courses. The first course aims, by a series of inspiratory exercises carried out in the recumbent position, at increasing the movement of the lower ribs and developing the inferior lateral region of the thorax. By this means the lower chest is expanded and the action of the lower part of the lungs improved. When this has been attained the patient is taught, in the second part of the course, to contract the abdominal muscles and drive the diaphragm forcibly upwards. By the combined movement he is educated to make the most of his lung capacity, and once thoroughly learnt the improved breathing becomes habitual. The result of this powerful increased respiration, inspiratory and expiratory, is to bring into play the large area of lungs towards the bases which is ordinarily unused, and so to add many millions of air cells to those already in action.

Work is less exclusively thrown on the upper part of the chest; the faulty tendency of the bronchitic towards

McMillingham, 1922

quick shallow breathing of the upper chest type is overcome; respiration is deepened and markedly slowed. It goes without saying that at the same time aeration and circulation, both of blood and lymph, are promoted; the nutrition of the lung is improved thereby, congestion and oedema disappear, cough is markedly diminished, and the heart is relieved. The total effect on the bronchi and lung is to bring the whole organ into that state of functional activity which stands for health and resistance to invading organisms.

In conclusion, while not undervaluing our present methods of treatment of chronic bronchitis, I beg to suggest, first, that important predisposing conditions are often present, the treatment of which is essential, and that medicinal measures, whether by drugs or vaccines, do not cover the whole ground; but that it is important by pure air, exercise, and even by special respiratory exercises, to maintain and increase the functional activity of the lung. On the one hand, by removing foci of infection, we can do much to prevent catarrh. On the other, after an attack, by enjoining, with suitable precautions, the value of pure fresh air and exercise of the lung, we can do much to defend the patient from sinking into a chronic

## II.—J. ODERY SYMES, M.D. LOND., Physician, Bristol General Hospital.

### THE VACCINE THERAPY OF CHRONIC BRONCHITIS.

If we exclude the chronic catarrhal conditions which arise from irritation by dust, or such as are seen in cardiac and renal conditions, we may regard chronic bronchitis as essentially an infective disease. The resistance of the individual is lowered by chill or by illness, and the organisms which are normally present in the nasopharynx are enabled to establish themselves in trachea and bronchi and set up inflammatory changes there.

It is my purpose to-day to discuss briefly the bacteriology of chronic bronchitis, and more particularly its treatment by vaccines. In no branch of vaccine therapy have I met with greater success than in the treatment of chronic bronchitis. Occasionally one fails to obtain a favourable result, but speaking generally an improvement may be assured and frequently a cure established. I have never seen a case made worse by vaccines. This favourable result has not been only in my own practice, but I have received, from the majority of medical men from whom I have inquired, reports which are very largely favourable to this method of treatment. Personally I am opposed to the use of stock vaccines, but I have received several reports from doctors who have found them invaluable both from a prophylactic and curative standpoint. The organisms most frequently responsible for the continuation of cases of chronic bronchitis are in their order of frequency the pneumococcus, various streptococci, and the *Micrococcus catarrhalis*. Pfeiffer's bacillus, Friedlander's bacillus, and staphylococci are also frequently found.

Unfortunately it is much more common to find two or three varieties of organisms in a sputum than to obtain what is practically a pure culture. It is this multiplicity of organisms in the sputum which militates against the success of vaccine therapy and which makes it imperative that peculiar care shall be taken in the collection and treatment of the material from which the vaccine is to be prepared.

#### Collection of Material.

In cases where sputum cannot be obtained satisfactorily—that is to say, where the mouth is septic or where for a time the bronchial symptoms are in abeyance—a nasal swabbing may be taken, as suggested by Mackey. He has shown that in cases of chronic bronchitis the exciting organisms are constantly present in the nasal passages, and there is less chance there of contamination with extraneous organisms.

#### Preparation of Vaccine.

In making a nasal culture it is well to introduce the swab through a glass tube which is inserted into the nostril and so protects it from contact with the skin, hair, and dried crusts, which are found at the meatus and which would otherwise be a source of contamination. West's swab,

as generally used for the nasopharynx, is excellent for this purpose. If the vaccine be prepared from the sputa then the patient should be directed first to wash out the mouth and to gargle with sterile water, and then to cough up and expectorate into a sterile vessel. It is better that these procedures should be carried out at the laboratory so that the plates may be inoculated immediately while the material is fresh and warm. If, however, this is not possible the tube or swab should be promptly sealed, placed in the waistcoat pocket, and at once conveyed to the laboratory. Any delay in the inoculation of plates—such, for instance, as is entailed by transmission by post—very much diminishes the probability of securing an efficient vaccine, for it may suffice to allow of the death of delicate organisms, and the multiplication of saprophytic varieties. The whole success of a vaccine may depend on this speedy transference of the material to the nutrient medium.

It is not my province to trespass on the technique of the bacteriologist, but I cannot leave this subject without saying that the preparation of the vaccine calls for much fine discernment and careful consideration. A film of the material should be stained and those organisms selected which are evident in the film and which show the freest growth on the various culture media. The vaccine should not be prepared from subcultures as this procedure much attenuates the strength of the organisms. If possible the bacteriologist should have the opportunity of seeing the sputum in bulk and should be given a history of the case. The manufacture of a vaccine for chronic bronchitis is an art—there are no set scientific principles—and some bacteriologists are more successful than others. From the foregoing it is evident that stock vaccines are not likely to meet with more than a modicum of success, and when it is remembered how many different strains there are of pneumococci and streptococci and how widely they differ one from the other, there can be no doubt that for successful treatment one must rely on the autogenous vaccine.

#### Dosage.

In the matter of dosage there is great variety of opinion, but one thing is essential—namely, that the dose be sufficient to excite reaction—a local reaction at the site of inoculation, and a mild general reaction—for example, malaise, slight rise of temperature, and a temporary increase of cough and expectoration. An overdose may result in a temporary set-back, and shake the confidence of the patient. It is well, therefore, to begin with small doses—say, 5 million of each organism—and gradually and at short intervals to raise the dose until a reaction is obtained.

The interval between the early tentative doses should be five days, and when once reaction is established this may be lengthened to seven days. If reaction is excessive, causing distress to the patient or a rise of temperature or more than 12°, the size of the next dose should not be increased, or the interval should be prolonged to ten days.

The essential point to remember is that the administration of the vaccine is not a mechanical process but a scientific procedure, requiring the same watchfulness and careful adjustment as the administration of digitalis in a case of failing compensation.

Vaccine treatment of bronchitis must be prolonged over a period of at least three months although the immediate symptoms may have disappeared, the object being not merely the amelioration of the present condition but also the establishment of a high degree of resistance. Preferably a new vaccine should be prepared at least once during such three months' course, as certain of the organisms which were originally present may have died out or fresh varieties may have supplanted them. In the same patient the bacteriology of successive attacks of bronchitis (winter recurrences) is seldom identical, so that it is no use relying for treatment on a vaccine founded on past experiences. One patient of mine, a lady whose chronic bronchitis is complicated by dilatation of the bronchi, has had vaccines prepared from her sputum or nasal passages on six occasions between 1910 and 1923. On each occasion the flora has been different—(1) *Micrococcus tetragenus* and streptococci; (2) streptococci and *M. catarrhalis*;

The newly emerged pupa measures about 3 mm. in length, is roughly club-shaped in outline, moist, glistening, and of a milky-white colour. The head and thorax appear fused in one mass which forms the head of the club. The handle of the club is represented by the abdomen, which tapers somewhat towards the posterior extremity. The outlines of the abdominal segments are seen as distinct ridges; only seven of the segments are visible, as the three terminal are enveloped by the remains of the fourth larval skin. The antennae are seen as curved ridges, one on either side of the cephalo-thoracic mass. The eyes are not visible at first, but after a few hours they appear as clusters of faint red dots, just below the curve of the antennae. These dots become more distinct and after in colour almost daily; they change in colour from light to dark red, brown, and finally become black. Moreover, the various parts of the pupa become more distinct daily. By the ninth day of pupal life the component parts of the imago can be clearly recognized, and pigmentation of the eyes and hairs is pronounced. The imago is now preparing to emerge from the pupal case.

The Pupa. (Plate II, Fig. 11.)

Emergence of the Imago. (Plate II, Fig. 12.)

Here again this further step in the life-cycle of the Phebotomus takes place between sunset and dawn; usually between midnight and 4 a.m., when the atmospheric humidity is between 60 and 50 per cent. The pupa periodically, with a flicking motion, bends its body backwards and forwards, the tip of a pale silvery grey colour. During the next two hours the dorsal cuticle which was previously present disappears as the pupa stretches out in its length. Suddenly a rupture of the pupal case occurs at the cephalo-thoracic junction, and the delicate white hairs which cover the thorax of the imago project through. The head is the first part born, then the antennae, one wing, abdomen, the other wing, and finally the legs. The insect works itself from side to side to free the various parts free, the whole process lasting about ten minutes.

The Imago.

The newly hatched imago is snowy white, except for the black piercing eyes. The body and wings are densely crumpled up, and held horizontally over the body. They do not dry and unfold until the atmospheric humidity decreases; this usually occurs within three hours after dawn. When the wings are dry they are raised at an angle of 45 degrees above the body, and the insect is able to fly. By this time the mouth parts are hardened and the creature is ready to feed (Plate II, Figs. 13 and 14).

The Act of Feeding.

Only the female Phebotomus bites. A feed of blood is absolutely essential for the eggs to become fertilized. If flies of both sexes are caged together, but are fed on earth and organic debris only, they never become pregnant; whereas those which are fed on blood become pregnant. The Phebotomus usually bites after sunset, unless strong winds have been blowing for a few days. In the latter case they are held captive in their bleeding haunts, and hunger causes them to seek a feed of blood at the earliest opportunity, night or day. Man is bitten wherever the skin is exposed, even through a thin sock. The Phebotomus alights with wings erect and body parallel to, but raised off, the skin on which it rests. The legs are gradually spread out so as to bring the point of the proboscis close to the skin; at the same time the labial palps are raised upwards and outwards; apparently the fly is sensing a vein, for it always pierces one with great precision. In this attitude it may make short runs over the body, if any. The palps are widely separated laterally and the proboscis is inserted into the skin for half to two-thirds its length. The actual bite is not felt, the pricking sensation is caused by the injection of saliva which takes place a few seconds later. This saliva delays the clotting of the blood. The blood is soon sucked up; within ten seconds it appears in the stomach. At the end of two and a half minutes this organ is so distended that it practically fills the whole abdomen. The abdomen is bent downwards so

Copulation usually does not occur until the second day of adult life. In the majority of cases (50 per cent.) the female has had a feed of blood prior to the act. The female feeds on the first day of life, and it is about twenty-four hours later before the process of digestion has lightened the joints sufficiently for the posterior end to be raised off the ground. The somewhat lightened female mounts to the higher parts of the room, for it is here the males congregate. Phebotomus, unless in copulation, are always found with their heads pointing upwards on a wall. The male Phebotomus approaches the female from behind and a little to one side, stands still, then gingerly swings his abdomen from side to side as if judging the distance. Suddenly he swings round through half a circle and grasps the posterior extremity of the female with his powerful claspers. The act of copulation lasts about thirty minutes. One copulation is sufficient to fertilize the female. The duration of pregnancy varies from seven to ten days; further feeds of blood may be partaken of, but are not necessary. Oviposition occurs about the ninth to tenth day of life and continues for two to three days; the fly usually dying in the process on the fourteenth day of adult life.

Process of Oviposition.

Oviposition takes place over a period of two to three days. If the fly partakes of a feed of blood when the ova are ready to be deposited the sudden increase of the intra-abdominal pressure causes the forcible extrusion of one or more eggs. The eggs may be ejected for a distance equal to that of the length of the fly (3 to 4 mm.). Usually the eggs are gently dropped just clear of the posterior extremity of the insect, singly at first with a period of half an hour to an hour between each. The following day the fly shows signs of exhaustion, the legs are spread out, the labial palps unrolled, and the wings droop to the horizontal position. Now the contractions of the abdomen become very spasmodic, and the posterior end is raised, the ovipositors widely opened, and the abdomen forced forward. This contraction is shortly followed by a sudden dropping of the abdomen. After several such contractions those eggs which remained in the ovaries are discharged in a mass—perhaps fifteen to twenty eggs. Thereafter the fly dies exhausted. The full complement of eggs in the ovaries is about forty. These are rarely all laid. The average number to expect from each female fly is about five—that is, after allowing for unsuitability of environment, sudden death, and non-pregnant condition of some flies. Of the eggs laid less than 50 per cent. reach maturity. These figures have been obtained from the results of repeated observations on thousands of flies.

A pregnant Phebotomus, when the ova are mature, must either deposit them or die egg-bound. If the atmospheric humidity is not fairly high (that is, above 65 per cent.) the fly does not oviposit. This fact has been established by keeping pregnant Phebotomus in test-tubes under various degrees of humidity. Granted the requisite amount of humidity the fly usually chooses certain situations. It obtains a moderate situation in some dark sheltered spot where there is nitrogenous organic matter and a moderate degree of moisture. Where soil is available the majority of the flies deposit their eggs underneath pieces of earth, stones, or insect remains. In such places the eggs are somewhat protected from dislodgement by air currents and heavy rains, and from the injurious effects of excess of moisture or undue evaporation. Phebotomus frequently deposit their eggs in garden soil, and in the loose earth at the foot of walls and buildings. The latter is an excellent site, for much nitrogenous organic debris is blown about by the wind gathers here, and the requisite moisture is obtained by the condensation of the atmospheric humidity on the walls. Loose earth, stones, and rubble of any sort provide breeding grounds, and flies have actually been found ovipositing on

## CONFERENCE ON INFANT WELFARE.

A CONFERENCE on infant welfare, called by the National Association for the Prevention of Infant Mortality and the National Baby Week Council, and attended by over 400 delegates, was held at Caxton Hall, Westminster, on July 2nd, 3rd, and 4th. The representatives of the British Medical Association were Dr. E. R. Fothergill, Professor A. Louise Mellroy, and Dr. D. H. Paterson. Two sessions each day were devoted to debates on the medical, social, and governmental side of the subject, two lectures intended for a wider audience were delivered each evening by medical men, and a number of tours were arranged to schools of mothercraft, day nurseries, and hospitals.

### *The Minister of Health on Present Needs.*

The conference was opened by the Minister of Health (Mr. Neville Chamberlain), who referred to the comparative newness of the subject in its national aspect; it really dated from the Act of 1918, which prescribed the duties of local authorities and resulted in an extraordinary growth of the work throughout the country. Infant mortality had fallen to about half the rate per thousand at which it stood a generation ago, and he regarded it as unthinkable that, even in the name of economy, the nation should retrace its steps. The Ministry was determined that the efficiency of this service should not be cut down. The number of infant welfare centres and of health visitors should be increased, because experience had shown that where health visiting was most complete, and where there was an infant welfare centre within fairly reasonable reach of every mother, the greatest reduction in infant mortality was forthcoming. Another matter of urgency was the further provision of maternity homes with the object of reducing maternal and infant mortality. The unwillingness of mothers to attend maternity hospitals for their confinement, partly on account of prejudice, and partly because they would not go long distances from their homes, pointed in the direction of a large number of small homes rather than a small number of large ones. The provision of a large number of small homes would mean increased capital outlay and maintenance costs, but he hoped that as the financial condition of the country improved it would be possible to face expenditure under this heading. There was need also for the better provision of trained midwives in rural districts; the difficulty here also was financial—that of paying higher salaries.

### *Causal Factors of Infant Mortality.*

The first discussion, over which Dr. G. F. Still presided, was on the causal factors of early infantile mortality. Dr. J. S. Fairbairn, in opening, said that roughly half the infantile mortality occurred in the first week of life, and was due to a bad start and not to mismanagement and lack of care after birth. Apart from birth injuries, the conditions causing early infantile deaths were chiefly comprised under the headings of maternal disease, prematurity, and foetal deformity. Prematurity was a large factor, and was partly the result of maternal disease. The supervision of pregnant women from as early in pregnancy as possible would diminish the number of premature births and births of feeble infants, but better co-ordination of ante-natal clinics with hospitals and other institutions capable of providing expert investigation and treatment was essential. He advocated strongly that all ante-natal clinics should be linked up with the scientific service of some of the large hospitals. Without this it was not possible for much reduction to be made in the incidence of premature and weakly-born infants.

Dr. R. C. Jewesbury presented statistics which showed that the recent reduction in infant mortality was most marked in the age-group between six and twelve months, and next in that between three and six months. Taking these two groups together, the death rate in infants between the ages of three months and one year had fallen from 47 in 1910 to 29 in 1920.

Dr. Donald Paterson said that less than 30 per cent. of the total number of neo-natal deaths investigated were unpreventable; in the remainder almost the whole of the causal factors could be disposed of, provided mother, midwife, and medical practitioner were continually on the alert. If the importance of breast feeding, the care of the child after birth, and the efficient treatment of syphilitic parents or prospective parents received serious attention, he held strongly that the neo-natal death rate should be reduced by at least 30 per cent.

Professor A. L. Mellroy maintained that hitherto overmuch attention had been focused on the baby, by which she meant that there had been too much interference with the natural processes governing the animal creation. A great deal could be done by sending properly qualified doctors and nurses to country districts.

### *The Value of Maternity Homes.*

Dr. W. Allen Daley (M.O.H. Blackburn) opened a discussion on the value of maternity homes in a maternity and child welfare scheme. He said that at a conservative estimate there were over 2,000 preventable deaths of mothers in childbirth every year, associated in the main with lack of skilled assistance when needed in pregnancy and at and after childbirth. There were relatively few such deaths in the metropolitan boroughs, and relatively many in the county boroughs of the north, where maternity hospital facilities were notoriously lacking. In view of the fact that so very large a proportion of expectant mothers in industrial areas consulted a midwife in the first instance, the efficiency of the midwifery service and the attitude of midwives towards the homes was all-important. Co-operation between midwives and ante-natal centres must be promoted by devices mutually beneficial.

Miss Wishart, matron of Queen Mary's Maternity Hospital, Hampstead, said that at the moment the practising midwife was not a little apprehensive of the gradual development of institutional treatment for her *clientèle*. Although the midwife welcomed the help of maternity homes in cases where complications were anticipated, or where the mothers could not have the care, feeding, and comfort necessary, she was, nevertheless, naturally anxious to retain those cases with which she could well deal. If maternity homes were indifferently equipped or staffed they would do harm instead of good, not only to the mother but to the baby. An outstanding advantage of the maternity home environment was the opportunity it gave for education.

### *Administration of Maternity and Child Welfare Centres.*

Dr. W. G. Willoughby (M.O.H. Eastbourne), in opening a discussion on this subject, said that it was the business of a child welfare centre to arrange that everything pertaining to the welfare of children from conception to birth, and from birth onwards, should have proper attention. A limitation of scope at present was the frequent lack of very early visiting in the homes by the health visitors after births had occurred.

Dr. E. R. Fothergill maintained that the objective of maternity and child welfare centres should be educational and advisory, and therefore preventive. No medical treatment should be given at the centre. When the expectant or nursing mother or the child required medical treatment, the fact should be communicated to the mother, with the advice that the family doctor should be consulted. In the case of the child, if the family doctor preferred not to undertake treatment, it would be treated at the clinic provided by the local authority. Clinics should be quite distinct from centres. With regard to the medical officer at the clinic, while specialism had its charms it had also its limitations. If the general practitioner were excluded, the better-to-do, who did not require attention at the centres or clinics, would be deprived of competent general practitioners to attend them in their homes. Every source of information and experience in the life of the community should be placed at the disposal of the general practitioner, who was the bedrock of the medical service of the country.

clothing and mosquito nets during the damp summer weather (sirocco). Experiments have confirmed these observations.

Earthenware pots were lined and covered with sterilized butter-muslin. These were placed in soup plates containing water, so that the lower half-inch of the pot was immersed. The water saturated the butter-muslin lining at the bottom of the pot; above this level varying degrees of moisture were obtained, depending on absorption by the muslin. Moreover, by evaporation of the water a high degree of humidity was obtained in the air in the pot. Phlebotomi were introduced and allowed to lay their eggs. When all the flies were dead the lining was removed and examined with a lens: 30 per cent. of the eggs laid were found on the muslin in the first inch, 42 per cent. in the second inch, 19 per cent. in the third inch, and 7 per cent. in the fourth inch above the water-line. Or, expressed in another way, 81 per cent. of the eggs were laid in the area from 1 to 2½ inches above the water-line.

In pots of similar construction, except that a plaster stand covered with some organic matter (earth and blood mixture, or insect remains) was placed in the bottom of the pot inside the muslin lining, most of the eggs were deposited in the organic matter; only 38 per cent. were found in the muslin.

These results show that a considerable degree of humidity is required for ovulation, and that the presence of nitrogenous organic matter creates a favourable soil.

It might be thought that those eggs that were laid on the muslin owing to the absence of nitrogenous organic matter would not mature. On the contrary, over 50 per cent. reached maturity in the normal time (nine to twelve days). Eggs laid in the second inch above the water-level hatched out first, then those in the upper part of the first inch, to be followed by those in the third inch, and in a few instances those in the fourth inch and lower part of the first inch. Many of the eggs that had been too dry or too moist failed to hatch. Most eggs will stand submersion for at least an hour, the result being a delay in maturation.

#### Movements.

The ovum is stationary, except for the rolling motion which precedes the hatching of the larva.

The larvae have a caterpillar-like motion. Their rate of progression varies with each stage of life and with the type of surface. The really active larvae are those in search of food, especially when in the last instar. The latter frequently attain a speed of 1 mm. in four seconds. The filamentous hairs and the sucker-like false legs on the under surface of the larvae give them a firm foothold. Various U-shaped and S-shaped attitudes are adopted by the larvae before and during each moult.

The pupa is fixed to some piece of earth, insect debris, or rock by the remains of the last larval skin. Now and again, from the action of such stimuli as changes of temperature and humidity, air currents, or chemicals, it moves the anterior part of its body. The movement consists of a series of quick backward and forward flicks, the body bending in the region of the fifth abdominal segment. These movements are most evident for a few hours before the imago emerges, but can take place from the earliest moment of pupal life.

The adult phlebotomus, when newly hatched, can only crawl. Later, when the wings are dry, it progresses by a short hopping flight usually to one side or other. The distance of a single flight is never more than four yards, and it does not travel more than fifty yards from its breeding haunts, probably less. This knowledge is important in connexion with prophylaxis.

The insect rests during the day and is active at night. It is attracted by the odours of man and other animals. Phlebotomi enter buildings by apertures in the walls—windows, doorways, ventilators, or even cracks. The females remain in the lower levels of the room in quest of blood, while the males collect near the ceiling to await the females for pairing purposes. The flight of the phlebotomus is so feeble that it avoids all currents of air, natural or artificial. There is a definite relationship between the force of the wind and the number of flies found indoors; roughly speaking, they are present in inverse proportion to the force of the wind. Upstairs rooms, which are more exposed to air currents, are less infested with phlebotomi than those on the ground floor.<sup>12</sup>

#### Food Supply.

The young larva, for the first few days of its existence, prefers soft earthy material containing nitrogenous organic matter. Later it is frequently found to devour the softer parts of the remains of insects. It thrives on mixtures of earth and human or sheep's blood, earth and human faeces, lizard's faeces, and ground-up cockroaches. This food material must have a thin film of surface moisture. A considerable number of larvae breed in the earth at the foot of walls and buildings—

situations where other insects and reptiles congregate and leave their faeces and dead remains. Moisture condenses on the walls at night, gravitates to their bases, and provides the necessary degree of humidity.

The adult fly, if of the male sex, feeds on any organic matter that it can suck up from the earth, vegetation, clothing, or even the sweat of man; it can exist for six days on water. The female phlebotomus can live on similar organic matter, but requires a feed of blood before she can become pregnant. The eggs of females fed on earth and organic debris only never become fertilized. *Phlebotomus papatasi* prefers the blood of warm-blooded animals; *Phlebotomus minutus* feeds chiefly on cold-blooded animals, but can feed on man.

#### Drying in the Shade.

The ova withstand drying in the air for a short time—about an hour.

The effect of drying on the larvae varies with their stage of development. When newly hatched the larvae, if allowed to dry, die almost immediately. Throughout the first and second instars the resistance to drying is not much greater, while the third and fourth stage larvae possess considerable powers of resistance. Such larvae have survived for three weeks without any addition of water to the shallow soil in which they lay, exposed to the air. These larvae eventually completed their life-cycle.

Pupa may be dried in the air for weeks and still retain their vitality.

The adult flies live longest, other things being equal, in a relatively dry atmosphere (40 to 50 per cent. humidity). The duration of life in such an atmosphere may be as long as thirty days, whereas in a moist atmosphere the flies rarely live longer than fourteen days.

#### Moisture.

The ova sink in water; submersion for twenty-four hours does not kill them, but delays their development. If left submerged for longer periods of time they do not mature. A fairly moist site is required for their healthy maturation. All stages of the larva sink in water after a few minutes. They do not withstand complete submersion for long, but partial submersion, such as would be experienced during the heavy rains, is endured for at least three consecutive days in the case of the larger larvae. The young larvae are less hardy.

The pupa does not withstand complete submersion in water for more than an hour. If kept covered with a thin surface film of water for three consecutive days it usually dies. Submersion in absolute alcohol took twenty minutes to kill one pupa.

Adult phlebotomi can live in a humid atmosphere, but, as has been stated, they prefer one which is relatively dry. These flies are killed almost immediately if water is sprayed on them; their wings are damaged, and probably also their delicate respiratory apparatus. Instinct apparently defends them, for they avoid skin that is bathed in perspiration, especially damp hairy parts.

#### Temperature.

The various stages of the life-cycle of the phlebotomus require an earth temperature (4-foot) of over 65° and under 80° F. for their healthy development. When the mean daily atmospheric temperature falls below 65° F. the adult fly cannot oviposit, but dies in a few days. An atmospheric temperature of over 90° F. is injurious to the adult. The optimum atmospheric temperature for all stages lies between 70° and 80° F. The insect hibernates in the fourth larval stage when the earth temperature falls below 65° F., and, as the shortest period of time in which the pupal state can be completed is nine days, the geographical distribution of the phlebotomus is restricted to places where the earth temperature (4-foot) is maintained above 65° F. for at least ten consecutive days.

It has been stated that the fall in the incidence of phlebotomi in July and August is due to the heat killing these flies; but this fall may be explained by the fact that during these months most of the summer brood are in the ovum, larval, or pupal stage. Thus the length of the life-cycle explains the two distinct waves in the incidence of the phlebotomus—the first in June, the second early in September.<sup>13</sup>

It is possible to prolong the larval stage considerably by the retarding effect of increased moisture or lower atmospheric temperature. In this manner several larvae have been kept in the fourth larval instar for six months, and then, by reducing the amount of moisture and incubating at 80° F., pupation has occurred. Adult phlebotomi eventually hatched out from these pupae.<sup>14</sup> This shows that *Phlebotomus papatasi* hibernates in the fourth larval stage—the stage which is best adapted to cope with the heavy rains and the cold of the winter months.

without the most searching examination—cystographic, and chemical—of the whole genito-urinary cases. He emphasized the bladder or kidney cases in his wards was thus made possible in which Mr. Galbraith in this work.

Mr. Galbraith said that the purpose of the report was to show that pyelography could be done without danger and with only a minimum of the patient and that it was a valuable aid to the physician in considering in detail the possibilities of the various conditions. (1) the possibility of making the injection, (2) sepsis, (3) trauma to the renal pelvis, (4) constitutional disturbance—how they had been eliminated by him. He emphasized the technique, emphasizing his opinion that this was unnecessary and in fact contrary to the usual practice. He said that a ureter catheter of larger size than No. 5 and this was passed, in the absence of an obstruction was the weight of the piston of a delicate 10 c.m. Record syringe held about two inches above the kidney, and the amount of fluid injected exceeded 5 c.m., unless the pelvis was distended by previous aspiration or pyelogram. The technique he had never found any ill effects, nor had any of the patients complained of discomfort other than that due to the cystoscope. Mr. Galbraith then showed a series of slides and the original films, illustrative of conditions in which pyelography had proved of value.

(1) Cases of typical renal colic pain in which the pyelography demonstrated the exact relation of the shadow in the region of the kidney to the kidney or ureter. (2) Cases of renal colic pain which was negative; here pyelography demonstrated the exact site of the shadow, thus facilitating at operation. (3) Cases of indurated urinary stricture with a negative x-ray and cystoscopic examination showed an abnormal condition of the renal pelvis, for example, to tumor. (4) Cases of kidney disease, more accurately determined. In the discussion which followed Dr. Leonard referred to the difficulty encountered in the method to children; and Mr. Archibald J. Mill, Rector, and Dr. John Ritchie also.

## TREATMENT OF CANCER OF THE BLADDER BY X RAYS.

A meeting of the Section of Obstetrics and Gynaecology of the Academy of Medicine in Ireland was held on the 11th of November, 1922, when Dr. Lewis T. Cassidy, with the President, Dr. Zwieter, read a paper on the treatment of cancer of the cervix uteri by deep x-ray therapy. Having described the apparatus Dr. Zwieter then described three different methods of treatment followed by either radium or x rays, or both. Of twenty-one gynaecological clinics in Germany the other six every patient was treated by radium. He pointed out that in Bunn's case

perium were uneventful. Mr. G. P. Newbould read a note on four cases of intestinal obstruction caused by gall stones. Three of the patients were women, all of whom recovered; one was a male, who died. The symptoms were those of intestinal obstruction. Faecal vomiting with intermissions was present. Comparison was not absolute and there was not much abdominal distension. The patients were all stout and elderly, one woman weighing 19 st. The chemical examination of the last stone removed was that of a typical gall stone.

Mr. G. C. E. Simpson said that he had seen two cases of this condition, both in women. One, aged 70, died of pneumonia after operation. In the other case gall stones were diagnosed but the vomiting passed so insensibly into the vomiting of obstruction that some days were lost: in the latter case on exploration the adhesion of the gall bladder to the duodenum angle was seen and two stones were felt firmly impacted low down in the common duct. Presumably the fistula first formed in the initial severe attack, the only attack accompanied by jaundice, six months before the big stone passed and gave rise to obstruction. Operation on the biliary region had not yet been undertaken.

Dr. C. O. Stammers read a paper on the recent outbreak of encoprophilia in Limerick. Having referred to the past history of the disease, he said that while it was not new its pandemic extension was a new feature. As the disease spread there had been observed in France, Italy, etc., a tendency to evolve from a type presenting depression of function to one exhibiting exaltation of function; instead of paroxysms, delirium, and somnolence, there were involuntary movements, delirium, and sleeplessness. In Liverpool, in 1921, 81 per cent. of the cases were of the first type. In the winter of 1922-23 a considerable outbreak involving over a hundred cases occurred and only 52 per cent. were of the first type. The delirium was usually occupational. Alteration in type was accompanied by increased fatality as well in the lethargic as in the overactive type; age incidence was identical in both types. A definite history of contact with a preceding case was found in 9 per cent. of the cases. Dr. Stammers described four abortive cases. The virus he regarded as a variable one which at times exhibited marked malignancy and increased pathogenicity, as at Derby, Radduwoorde, and, probably, at

Dr. A. G. Gellman said that he had first seen cases of encoprophilia in Limerick at the end of 1919, when they were of the lethargic type, and though they were not paralysed the patients lay motionless in bed, were only roused with difficulty, and spoke in a monotonous, toneless voice. The only sign of interest the patients showed was by asking in a feeble voice "whether they were going to recover." He agreed that the expressionless face was the most characteristic symptom of the disease, both in the lethargic and in the restless varieties. In 1922 he saw a considerable number of cases of the excited form in which choreic movements, wakefulness, and in some instances occupational delirium were present. Dr. Gellman added that his mortality was considerably lower than that given for the whole of Liverpool: at the present time he had in his wards a case of the lethargic type which gave a previous history of trauma.

## PSYLOGRAPHY.

At a meeting of the Royal Medical-Chirurgical Society of Glasgow held on November 16th, with Dr. Leonard and Dr. Walter W. Galbraith, Vice-President, in the chair, Mr. Walter W. Galbraith made a communication on psychography.

*Habitats.*

In nature the larval and pupal stages are found in the cracks of embankments, in the loose earth at the base of walls and buildings, in cultivated soil, and in other places where suitable conditions of food, moisture, and temperature exist. Larvae are found even to a depth of a foot or more in loose soil; they are freely mobile, and can migrate to the level of optimum environment. When ready to pupate they seek a drier spot, so that the pupae are usually found within a few inches of the surface of the ground.

*Phlebotomus papatasi* is directly responsible for the conveyance of phlebotomus fever to man. Prophylactic measures against this fever must be directed upon the fly. It is only by having a sound working knowledge of the life-history and bionomics of this insect that these measures can be applied successfully and economically.

*Acknowledgements.*

The Royal Air Force Sandfly Fever Commission is greatly indebted to Colonel Sir Matthew H. G. Fell, K.C.B., C.M.G., late Director of Medical Services, R.A.F., for the inception of this work; to Air Commodore D. Munro, C.I.E., F.R.C.S., the present Director of Medical Services, and to Group Captain M. W. Flack, C.B.E., Director of Medical Research, for constant advice, friendly criticism, and the provision of much necessary apparatus; to His Excellency the Governor of Malta, Lord Plumer, G.C.B., G.C.M.G., G.C.V.O., for his keen and stimulating interest in these researches, and for his help in co-ordinating this work with that of the other services and civil authorities; to Air Commodore C. R. Samson, C.M.G., D.S.O., A.F.C., Air Officer Commanding Mediterranean Forces, for granting every facility for carrying out the investigations; to Squadron Leader P. Shepherd, R.A.F., Officer Commanding 257 Squadron, Calafra, for the provision of the laboratory and other accommodation, and a free hand to carry out experimental measures at his station; also to Flight Lieutenant R. Stewart, R.A.F., who performed similar courtesies during the absence of the C.O.; to Squadron Leader T. J. Kelly, M.C., R.A.F.M.S., Senior Medical Officer Mediterranean Area, for valuable co-operation; to Flight Lieutenants V. R. Scriven, A.F.C., F. A. Norton, Flying Officers F. H. H. Twelvetree and W. R. Heywood for continued assistance in the construction of various instruments and apparatus; to Mr. Harwood, Superintendent of the Meteorological Office, for continuous meteorological observations, which were of great assistance when breeding the phlebotomus; to Mr. G. C. Sinclair and Mr. Hooper for invaluable services in erecting and fitting up the laboratories and apparatus required throughout these experiments; to Major-General Sir William B. Leishman, K.C.M.G., F.R.S., Director of Pathology; Colonel W. P. Gwynn, C.M.G., D.D.M.S., Malta; Majors M. B. H. Ritchie, O.B.E., D.S.O., and R. E. U. Newman, O.B.E., M.C., and other officers of the R.A.M.C. for placing their stores, hospital and laboratory material at our disposal; Colonel Dundon, Minister of Health to Malta, and Dr. Critien, Principal Medical Officer of Health, for kindly advice; and to Dr. Salvatore De Bono for help in translating Italian manuscripts. In conclusion we desire to thank Corporal R. Stewart and Leading Aircraftman H. A. Collett, R.A.F.M.S., for loyal support in many arduous duties throughout these experiments.

## Memoranda:

## MEDICAL, SURGICAL, OBSTETRICAL.

## THE FIBULA AS A BONE GRAFT FOR UNUNITED FRACTURE OF THE NECK OF THE FEMUR.

A young adult male suffered a fracture of the neck of the left femur in a railway accident. After nine months, in spite of immobilization in a Thomas's hip splint and walking exercises in a calliper splint, there was no evidence of union. The usual causes of non-union of fractures in Egypt—syphilis, ankylostomiasis, and bilharziasis—could be eliminated.

At operation, under storaine anaesthesia, the glutei muscles were reflected upwards by chiselling through the tip of the great trochanter. The joint was then exposed from above and the loose head of the femur secured by lion forceps. A hole was drilled, by an electric burr, through the base of the great trochanter and the neck of the femur into the cancellous tissue of the head of the bone. A length of the fibula, previously removed with its periosteum intact, was then driven through the hole into the head of the femur.

No splint apparatus was applied; but the patient was encouraged to move the quadriceps and, finally, to perform all the movements of his leg while lying in bed. The strength of the fibula was sufficient to give the necessary stability to the neck of the femur to allow of these movements. Radiographs taken at regular intervals showed new formation of bone and a progressive attenuation of the graft. At the end of two months, the muscles of the leg being in excellent condition, the patient was allowed to walk with a crutch. At the end of three months he was walking upstairs and down by progressive steps and without any support. The hip-joint allowed voluntary flexion to 45 degrees. There is shortening to the extent of one inch.

The conclusions to be drawn are: (1) That access to the hip-joint by this method of approach is easy. (2) That the loose head of the bone can be simply secured while the cancellous bone is being drilled. (3) That early and complete mobilization by voluntary movements without massage is valuable. (4) That new bone develops rapidly as a direct result of the presence of the graft and the trauma occasioned by the bone drill. (5) That storaine anaesthesia almost completely eliminates surgical shock. (6) That this method of bone grafting is, as compared with others, relatively easy.

R. V. DOLBEX, M.S., F.R.C.S.,  
Director of Surgical Unit, Egyptian Government  
School of Medicine, Kasr-el-Aini  
Hospital, Cairo.

## INTESTINAL SPASM DUE TO ASCARIS LUMBRICOIDES.

I OPERATED recently upon a boy, aged 12, for appendicitis. After cutting through the abdominal wall and opening the peritoneal cavity I pulled up into the wound a piece of small intestine which presented an unusual appearance. The bowel appeared to be in a state of spasm, the free border forming a firm, hard, rounded cord about three-eighths of an inch in thickness; the rest of the walls were in accurate apposition. This condition was traced above and below for about ten inches in all, the "cord" tapering off at each end. The intestine immediately above and below was quite normal. The cord-like appearance was due to the wall of the bowel at its free border firmly embracing an *Ascaris lumbricoides*.

I record this case because such a phenomenon may have been rarely seen. Although we know that "worms" produce colicky pains and other dyspeptic and nervous symptoms, yet few can have realized that an *Ascaris lumbricoides* could give rise to a spasm causing a total though transient occlusion of so great an extent of the intestine. Surely this must mean some considerable functional disturbance, either directly or reflexly, of the digestive tract, and emphasizes the necessity, in the interests of the patient, of an early diagnosis and removal of these parasites.

H. ELWIN HARRIS, M.B., F.R.C.S. Eng.,  
Consulting Surgeon, Bristol Royal Hospital  
for Sick Children and Women.

in a long series of cases the percentage of definite cures after operation had been doubted by post-operative x-ray treatment. The unit skin dose of x rays was that which after six to eight days produced a red discoloration of the skin and after three to four weeks produced tanning. If this unit skin dose was represented by 100, then the cancer dose, as determined by Seitz and Wintz, was from 50 to 110. The depth of the cervix from the abdominal wall was from 7 to 10 cm., and experiment had shown that at that depth the effective dose was 20 per cent. of the surface dose, so that the rays had to be concentrated from six or seven fields in order to get the cancer dose at that depth. As it was not possible by that method to radiate the whole pelvis cavity effectively at one sitting, the tumour itself was irradiated first, and after about six weeks' interval the parietal cavity was treated. The duration of the radiation for each field was about half an hour. The after-treatment was of great importance, as cure depended upon the ability of the organs to react against the cancerous disease. The treatment was attended with considerable risk to both the operator and the patient, and should be regarded as a major operation.

Of all patients treated for cancer by deep therapy about 20 per cent. could be cured, and of all operable cases about 50 per cent. could be cured for five years or longer. When cure was not obtained great relief from the symptoms was obtained.

Dr. Maurice Haves said that deep x-ray therapy was not new. The only new thing was that with improvements in the apparatus they were now able to produce a more penetrating ray than formerly. They were now working with apparatus which could produce continuously a voltage of about 200,000. Dr. Zweifel had sounded a note of warning which he was glad to hear. Deep x-ray therapy was a major operation, but the shock after the treatment, which was as great as that which followed hysterectomy, depended more or less on the method in which the therapy was produced.

Dr. Prieser (Birmingham) said that he thought x rays could be considered as a medicament, and that there should be certain doses for the different parts of the body. This dosage had of late years been more accurately determined than formerly, but there were still great difficulties to be overcome in connexion with it, and they were really still in the dark on the subject, as all they knew was that a certain amount of x rays would produce a certain amount of cure. Certain doses had been determined for certain parts of the body, but it had still to be determined which doses gave the best percentage of cures. The human body was a very complex construction, and therefore it was very difficult to be sure whether one was giving the right dose or not. In cases in which it were possible he thought an operation should be performed before treatment by x rays was tried, unless a very extensive operation would be necessary, the result of which would be uncertain, and in such cases treatment by x rays should be considered. It was not a question of competition between operative treatment and x-ray treatment, but a question of doing whichever it was thought would be best for the patient.

C. M. O'BRYEN, Dr. W. C. STEVENSON, and Dr. J. G. HARDMAN also took part in the discussion, and a vote of thanks to Dr. Zweifel was unanimously carried.

A meeting of the Birmingham and District Medical Women's Association was held on November 17th, when Dr. Mary Gordon, late H.M. Inspector of Prisons, spoke on analytical psychology. She referred to that large unexplored territory of the mind now recognized as functioning unconsciously, and to the valuable contributions that had been made to the knowledge of psychology through the researches of scientists in every field. Modern psychology signified it was, as yet, little understood, it had already thrown a flash of expectancy round the world. Dr. Gordon referred to the dislocations of all kinds met with in those who were, in some way or another, in the power of the unconscious, and which brought the sufferer to the medical practitioner. Life could only be understood by living it. Dr. Gordon explained the four orientating mental functions—thinking, feeling, intuition, and sensation—and showed how the almost exclusive use of one of

## Rebels.

Dr. Arthur Shadwell's new book *Drink in 1914-1922: A Lesson in Control* is an important contribution to the study of the problems raised for the whole community by the misguided individuals who indulge unduly in alcohol. It gives a general account of the measures of control taken in this country during the war, and though other writers have dealt with the subject previously, and most of the figures given are available elsewhere, the author's judgments upon the results attained by control are of very special interest, because he has devoted many years to the study of temperance reform, and what is most important, still finds it possible to write as a man of science rather than as a propagandist. This is a rare virtue in publication, dealing with drink control legislation, for, as Dr. Shadwell says, "I know of no field of legislation in which the teaching of experience is more needed, yet more often subordinated to fancy, prejudice, and interest."

The main portion of the book consists of an admirably clear history of the reasons why control was instituted in 1915, of the successive measures of control adopted, and of the results produced by these measures. A final chapter is devoted to a consideration of the lessons which the author considers these experiences teach, various important memoranda, orders, and statistics are given in appendices.

The history of the origin of drink control shows very clearly that it was adopted at the urgent instance of the naval and military authorities as a measure necessary for the successful prosecution of the war. The difficulties of the Control Board are traced, and it is made plain that pressure was constantly being brought to bear on it to go beyond measures of simple military necessity, and to strain its authority in the interests of teetotalism: the people accepted control up to a certain measure without opposition other than the grumbling which is a traditional British privilege, but when control had been carried to a certain point any further restriction aroused very keen opposition.

Considerable attention is devoted to the Carlisle scheme, its successes and disappointments. The author gives a qualified approval to the scheme; he admits that it produced a great improvement, but compares post-war figures for drunkenness in Carlisle and comparable towns, and concludes "that the special conditions of the trade in Carlisle have not produced any distinct or corresponding effect in the improvement of public order." It is not suggested that the reforms in Carlisle have produced no benefit, but the figures seem to prove that they have not improved drunkenness. This result, which, as the author remarks, has been a surprise and a disappointment, must be taken as proof that improvements in public houses, reductions in their number, and increased facilities for the sale of food in licensed houses cannot be expected to produce any striking increase in sobriety. The debateable point is, of course, whether the figures of convictions for

*Drink in 1914-1922: A Lesson in Control*, By Arthur Shadwell, M.A., M.D., LL.D., F.R.C.P. London: Longmans, Green and Co. 1923. (Penny 8vo, pp. xi + 252, 10s. 6d. net.)

### TWIN PREGNANCY IN A BICORNUATE UTERUS WITH CONTRACTED PELVIS: DELIVERY BY CAESAREAN SECTION.

A HINDU woman, aged 38, full-time pregnant, was admitted to hospital on April 6th, 1922, labour having begun twenty-four hours previously. She had had two previous labours: (1) the child died soon after birth; (2) a breech, in which there was difficulty with the after-coming head and the child was born dead.

On admission the patient's general condition was good; the abdomen was very large, and two foetuses could be distinctly felt. Per vaginam the os was found to be fully dilated, the membranes ruptured, and the breech of the first child presenting. The sacral promontory was within easy reach of the finger; after labour the true conjugate was estimated as 3 inches. As a living child was very much desired I decided on delivery by Caesarean section.

On opening the abdomen the appearance at first suggested a normal full-term uterus and a large tumour or cyst; this latter proved to be the second horn of a bicornuate uterus. The two horns appeared equal in size, and separation occurred about a handbreadth below the round ligament. The lower uterine segment was distended by the breech of the first child. A living male child was delivered from the left horn of the uterus and the incision closed before opening the right horn. On opening the latter the membranes were found unruptured, and a second living boy, also presenting by the breech, was delivered. The second incision was then closed.

The patient made an uneventful recovery, and she and both children were doing well when discharged from hospital at the end of three weeks.

J. LAMB, M.B., B.S.,  
St. Catherine's Hospital, Amritsar.

### PRELIMINARY NOTE ON THE X-RAY TREATMENT OF INTERSTITIAL KERATITIS.

Our interest in the treatment of interstitial keratitis by x rays was aroused by an article by Japiot and Bussy.<sup>1</sup> Several cases have now been treated for us by Dr. Oram, honorary radiologist to the David Lewis Northern Hospital, Liverpool. All attended St. Paul's Eye Hospital and received the usual treatment for interstitial keratitis during the course of x-ray therapy. The action of the rays has proved a beneficial adjunct to the usual treatment, and the response has been more noticeable in patients over the age of puberty. The results encourage us to make further use of this method of treatment. On the suggestion of one of us, other surgeons are now, we believe, trying this treatment. Three cases might be recorded here:

1. A man, aged 22, under the usual treatment to the right eye from February 13th to August 24th, 1923; he then went back to his work. On October 19th he reported again to St. Paul's with the left eye affected. From the first x-ray therapy was combined with the usual treatment, and after three x-ray treatments he returned to his work and expressed himself as delighted. There has been no relapse to date.

2. A girl aged 16, a typical and very severe case, after five treatments by x rays had no photophobia and was able to recognize her friends easily and considered herself "quite well."

3. A girl, aged 15, has had four x-ray treatments and has improved so rapidly that the mother volunteered the statement that no treatment previously received by the girl had made such a marked improvement in the condition.

Dr. Oram reports particulars of the dosage: Five minutes' exposure once weekly; 5-inch spark gap; 1 milli-ampere of current; 9 inches from the anticathode to the eye filtered through 1/2 mm. aluminium and two felts.

H. HAWARD BYWATER, M.D.,  
F.R.C.S.E., D.Ch.O., Honorary Surgeon,  
F. C. PLUMMER, M.D.,  
Honorary Assistant Surgeon,  
St. Paul's Eye Hospital, Liverpool.

## Reports of Societies.

### INTRACRANIAL HAEMORRHAGE IN THE NEWBORN.

THE Medical Society of London held a discussion on "Intracranial haemorrhage in newborn children: its pathology, effects, treatment and results," on December 10th. The President, Dr. HERBERT SPENCER, occupied the chair.

Mr. EARDLEY HOLLAND, in opening the discussion, said that as an obstetrician he had been chiefly interested in the etiology and pathology of intracranial haemorrhage. He referred to the excellence and importance of Dr. Herbert Spencer's work<sup>1</sup> on visceral haemorrhages in stillborn children. He proceeded to give in outline an account of the mechanics of traumatic intracranial haemorrhage which he has so fully considered in his admirable report to the Ministry of Health.<sup>2</sup> His remarks were well illustrated by epidiascope reproductions of drawings and diagrams which have already been published in the same report. Cranial stress consisted of a general compression of the whole head, and a simple longitudinal compression by opposite forces acting at the ends of the long diameter of engagement of the head in the pelvis. The more rapidly these forces were applied the more serious was their result. Excessive stress led to an overstretching and tearing of the tentorium cerebelli and falx cerebri, and to the rupture of certain blood vessels. The commonest site for tears was in the tentorium at its junction with the falx. The changes in the septa were transmitted to the vein of Galen, which became stretched, kinked, and engorged; the consequent rupture of this vein or of its tributaries resulted in subdural haemorrhage of greater or less extent. Normally the septa exerted a protective function in labour, by preventing excessive alterations in the shape of the foetal head. With this object they contained special strengthening bands and fibres, beautifully arranged on mechanical principles along the lines where stress was likely to fall during moulding of the head. Antero-posterior compression of the head and the consequent vertical elongation were particularly dangerous, and application of forceps to the antero-posterior diameter always involved considerable risk. The risk of applying forceps to the extremely plastic head of a premature foetus was well known. In all cases of forceps delivery the degree of stress obviously depended on the amount of force exerted. In breech deliveries the high percentage of intracranial injuries was probably to be explained by the rapidity with which forces were frequently brought to bear on the structures concerned. A less common cause of intracranial haemorrhage was foetal asphyxia, which might lead to venous congestion. Pressure on the umbilical cord or separation of the placenta presumably gave rise to an accumulation of carbon dioxide in the foetal blood which stimulated respiratory movements. Such respiratory attempts on the part of the foetus would lead to a partial closure of the ductus arteriosus, and about half the blood in the right auricle would be dammed back; the lungs not being expanded, the circulation of this blood through them would be obstructed, and in consequence there would arise a most intense venous engorgement. Intracranial haemorrhages of this type were usually associated with multiple haemorrhages in other organs.

The actual sites of intracranial haematomata produced by one or other of these causes were of interest; but exact diagnosis was extremely difficult during life. They were not usually definitely circumscribed, indeed they were commonly multiple and diffuse. Operative treatment, for this and other reasons, was not hopeful. Lumbar puncture was only of temporary value.

Dr. H. C. CAMERON dealt with the after-history of such infants as survived. Obstetricians in this and other countries had demonstrated the frequency of intracranial haemorrhage in infants born dead or moribund, and it had

<sup>1</sup> *Trans. Obstet. Soc. of London*, 1922, vol. xxxiii, "On Visceral Haemorrhages in Stillborn Children."

<sup>2</sup> *Reports on Public Health*, No. 7, "The Causation of Foetal Death," by Eardley Holland, Ministry of Health, 1923.

been commonly believed that certain cases of cerebral diplegia represented some part of the survivors of this form of injury at birth. Little himself had advanced this view. Present-day neurologists, however, as represented by Collier, tended to regard cerebral diplegia as due to a primary error of development pre-natal in origin. It might be argued that intracranial haemorrhage was invariably fatal at or shortly after birth, but his (Dr. Cameron's) experience of infants and children had impressed upon him the essential soundness of Little's contention. The immediate signs of large subdural haematomata were well known. A day or two after birth the majority of cases showed retinal haemorrhages and oedema of the optic disc, and certain characteristic symptoms. The seriousness of the condition was most clearly indicated by impairment of two vital functions—sucking and breathing; the suction reflex was entirely absent. Attempts were being made to localize the sites of haemorrhage with a view to surgical relief. The obstetrician dealt only with the beginning of the story; the neurologist only with the end. For the intervening period reliance must be placed on the general practitioner and the pediatrician. The latter was usually called to see a newborn infant only when immediate death was feared or expected. A skilled investigation of any infant whose well-being gave rise to doubt was surely indicated by the observations of Mr. Holland. Prematurity or feebleness alone must not be regarded as a sufficient explanation of the failure to suck, of asphyxia, or of insomnolence. The nature of the labour was rarely indicative of the infantile lesion; the symptoms exhibited by the child itself had far greater significance. A history of constant screaming or of stupor, of aphonia, refusal to suck, rigidity, convulsions, asphyxia, facial or oculo-motor paresis or twitching, was extremely suggestive, but unfortunately, from want of early examination, rarely attainable. Observations on the colour of the stools were too frequently substituted for a routine physical investigation. A further difficulty was afforded by the long latent period which ensued after recovery from the immediate symptoms before the after-effects were commonly appreciated. Those parts of the brain which controlled complicated motor activity and equipose of the body were not developed at birth, and, as these particularly were the areas affected in non-fatal cases of haemorrhage, the backwardness of the child was not generally recognized until a year or more had elapsed. The term "Little's syndrome" was properly applied to two groups of cases and to two only. First, to cases of paraplegic rigidity without mental defect and without convulsions; secondly, to cases of general rigidity usually without convulsions and without mental symptoms or with only that degree of backwardness which was accounted for by delay in the auto-education proceeding from grasp and touch. The treatment of the first group was generally orthopaedic, and no question of mental defect arose. It was only when the hands had become stiff, immobile, and anaesthetic that an appreciable delay in the mental development of the child resulted. When, in addition, the face was stiff and immobile, when speech was long impossible, and when the laugh and cry were expressionless and not charged with emotion, the stimulation of gross idiocy or imbecility was close. Yet these children were not idiotic; their backwardness was due to sense deprivation, the sense of touch. Their intelligence was always much greater than would appear from a cursory examination. The ultimate result, compared with the initial backwardness in achieving voluntary control of movement, was often surprisingly good. It was possible that neurological studies held to prove the negligible bearing of birth trauma on cerebral diplegia had been based on material derived from very different sources.

Dr. Cameron illustrated his graphic description by demonstrating a well marked case of general rigidity whose mental development he had been able to trace and follow.

Mr. LAMING EVANS gave an outline of the treatment and results of treatment from an orthopaedic point of view. He referred to the question which had been raised by previous speakers as to the origin of the spasticity, and regarded it as important to decide whether this was primarily due to intracranial haemorrhage or to a fundamental nervous lesion. He proceeded to describe the common deformities of the upper and lower extremities which were presented to the surgeon for treatment.

Children were brought to him between the ages of 2 and 18. He stressed the value of accessories to purely surgical measures; it was essential to pay strict attention to hygiene, and especially to the general and physical education of the subject. Muscle education was a factor of first-class importance. In his experience electrical stimulation had proved useless in these cases. He described the merits and demerits of various appliances, and discussed operative procedures in some detail. Foerster's operation—the resection of posterior nerve roots—had now been generally abandoned in the treatment of this condition. In certain cases a plastic operation was advisable, and attention was directed chiefly to the muscles and tendons; in other cases the nervous system formed the centre of attack.

Mr. H. A. T. FAIRBANK considered the actual origin of the deformity to be immaterial so far as the orthopaedic surgeon was concerned. He regarded three years as the optimum age for operation. It was extremely desirable that the child should have been encouraged to make some attempt to walk and co-ordinate its movements beforehand. At a later age the condition naturally became more difficult to treat. There were several contraindications to operative measures. Education was invaluable. The nature of the operation varied; it was impossible to prescribe set operations to meet different types of case; each individual should be considered as a separate problem, and a surgical attack planned according to its particular features. The most satisfactory operation to correct the adductor deformity of the lower limbs was usually excision of the obturator nerve.

Dr. L. G. PHILLIPS referred to necropsies made at Queen Charlotte's and St. Mary's Hospitals in a hundred cases of foetal death. In twenty of these intracranial haemorrhage had been found. Premature delivery was an important factor; apparently it multiplied the foetal risk in this respect by four. As a result of the observations it seemed clear that the induction of labour should not be undertaken before the thirty-fifth or thirty-sixth week of pregnancy, and that forceps should not be applied in the delivery of premature infants. Four of the cases of intracranial haemorrhage had occurred in cases of toxæmia of pregnancy. To explain these Dr. Phillips postulated a defect of the endothelium of the blood vessels; in his opinion a similar defect characterized and resulted from the toxæmias of pregnancy in general. The prevention of intracranial haemorrhage in the foetus was to be attained by prevention of ante-partum and intra-partum asphyxia and of the development of toxæmic conditions in pregnancy. Forceps deliveries should be reduced to a minimum.

THE PRESIDENT congratulated the speakers on their investigations and the lucidity of their observations. He introduced certain points which had occurred to him in the course of his own researches. One potential factor in the production of intracranial haemorrhage in the foetus appeared to be a depression of the lower angle of the parietal bone in difficult labour; in obstructing one of the most important veins in the head this would lead to local engorgement and consequent haemorrhage. His original investigations had been directed towards the study of visceral haemorrhage in general, and, in spite of the particular subject of discussion, he felt justified in referring to a line of research which appeared to him to be of considerable interest and importance—namely, a study of the condition of the testes in cases of foetal death. This might have an important bearing on one aspect of the problems of sterility.

Mr. EARDLEY HOLLAND, in replying, referred to the main point raised by Dr. Cameron. He thought it inevitable that some children suffering from the milder degrees of intracranial haemorrhage should survive. Certain infants had lived for a week and had then been found *post mortem* to have had enormous haemorrhages. If these were not immediately fatal it was impossible to believe that lesser haematomata should be incompatible with a continued existence. He had been very interested to see the cast of an asymmetrical head which had been demonstrated by Dr. Cameron, and from previous experience judged that the abnormality had been accompanied by a tentorial tear.

noted above, says that injections are indicated for moderate haemorrhoids, but not for large hypertrophic, inflamed, strangulated, and prolapsed haemorrhoids, nor where local complications exist. Mr. Lockhart-Jones's opinion is that injections are convenient, and within certain limits and in selected cases the results are very good. They are useful when operation is contraindicated, but the haemorrhoids recur after short intervals. He has never seen any serious complication from injections, which, however, are contraindicated when there are more than three haemorrhoids, when they are large and prolapsed, and when there is haemorrhage or other rectal complication.

Mr. Morley is not precise enough in stating to what degree he selects his cases and the exact indications for injection. In comparing it with other operations it is to be remembered that the latter include cases which are too bad for injection.

### THE LONG AND THE SHORT OF IT.

PROFESSORS CZERNY and KETLER have commenced the publication of a second edition of their immense work, *Das Kindes Ernährung, Ernährungsstörungen und Ernährungs-therapie*. The present volume of 628 large and closely printed pages has for its title *Ernährung des gesunden Kindes*. The reader of their book

may well exclaim with Gremy, "O this learning; what a thing it is!"

The earlier chapters deal with the first day of life, with the examination of the newborn child, with the questions of maternal and weaning and of artificial feeding which then come up, and with the physiological conditions of the infant at birth and in the succeeding days. A very full examination is then made of human milk from the earliest stage of lactation to the close, with the variations in its chemical composition and quantity; of cows' and other mammalian milks; of the derivatives of cows' milk; and lastly of the farmacoeus and vegetable foods used in the first year. The details and technique of feeding by the breast and bottle are then given, with illustrative charts from many authors of the weight curves under these different types of feeding. The closing chapters deal with the chemical composition of the body as a whole, both in normal and in certain morbid conditions, and give a full account of the digestive secretions and glands, of the bacterial flora of the alimentary tract, and a complete examination of the urine and feces.

It will be seen from this brief description that the book is an unusually complete presentation of a large and complicated subject, and that it is valuable as a work of reference rather than as a practical manual of infant feeding. For in it all the important data of the subject have been gathered together from the literature of two continents. Facts, statistics, and tables are set down in ordered ranks, and the reader himself can judge from their agreement or discrepancies to what practical conclusions they lead. The book has its value as a storehouse of physical and chemical data on the metabolism and nutrition of the infant, and a high tribute must be paid to the industry and patience of the authors. As a work of reference it suffers from the lack of an index. The list of chapters headings given is only a general guide to the contents;

*Das Kindes Ernährung, Ernährungsstörungen und Ernährungs-therapie*. Von Professor Dr. Czerny und Professor Dr. Ketler. Zweite vollständige Auflage. I Band. I Teil. Leipzig und Wien: Franz Deuticke, 1923. (Sup. roy. 8vo, pp. 623; 84 figures.)

*What is Man?* By J. Arthur Thomson, M.A., LL.D. London: Methuen & Co., 1923. (Cr. 8vo, pp. 241, 6s. 6d. net.)

*What is Man?* By J. Arthur Thomson, M.A., LL.D. London: Methuen & Co., 1923. (Cr. 8vo, pp. 241, 6s. 6d. net.)

*South*. By Dr. Jean Frommann, with a preface by Jean Frommann. Translated from the French edition by Elaine A. Wood. Sixth edition. London: John Bale, Son, and Dancelsen, 1923. (Cr. 8vo, pp. viii + 123, 7s. 6d. net, postage inland 6d.)

The book on the diagnosis and treatment of diseases of children by Dr. F. Lister of Karlsruhe has reached its third edition. It is a condensed account of the subject, and is arranged on the usual plan; it begins with a short account of the physiology of growth, proceeds to the feeding of the healthy infant, and then deals with diseases. The deliberate plan of compression has no doubt its attraction and value, and reference is facilitated by good indices. Very little is said of pathology; important symptoms are detailed in a somewhat disconnected way; but considerable care and space are devoted to treatment. Indeed, once the difficulty of diagnosis is passed, the book affords reliable section of the book includes a full pharmacopoeia with instructions for the preparation of food materials, and a list of Continental sanatoriums and health stations for sick children.

The present volume of 628 large and closely printed pages has for its title *Ernährung des gesunden Kindes*. The reader of their book

*What is Man?* is the title of Professor J. Arthur Thomson's lecture—the third course of "Thomson Lectures" he has given at Aberdeen—on the aspect of man according to biological, physical, and mental, is discussed from many points of view, coming and giving descriptions of the known early types. Man's body is described as a walking museum of relics of which Wedersheim gives a list of fifty, ontology recapitulating phylogeny. Such vestigial remains are said to be prone to disease and infection, and Professor Thomson regards man's alimentary canal as much too long and the colon as in some measure an anachronism. Following Mr. Morley Roberts' *Manure in the Human Body*, he recognizes some hostility between the constituent parts of the body, and remarks that, although a compromise may be effected, control may be disturbed, and that such a loss of equilibrium between epithelial and connective tissue is the underlying factor in malignant disease. Old age is differentiated from senility, which is a degenerative process started hardly ever to occur in wild nature, man and domesticated animals having almost a monopoly of this disharmony, which is a penalty for human complexity. Senility and disease are regarded as the results of man's rebellion against Nature's regime and misdeeds such as his indulgence in various forms of excess.

The volume entitled *Rejuvenation* is a translation of a popular work by Dr. JEAN FROMMANN, which reached its fifth edition in the space of a year and a half. It has an optimistic preface from the late Dean Flint, the author of a book on the philosophy of longevity. Frommann's book is obviously intended for the lay public and contains much sound advice about the laws of physiological righteousness. The errors common in ordinary life, such as fear of light and fresh air, and excesses in diet, drink, and tobacco, are emphasized, and the view that there is any real correlation between the dated age and the age value of an individual is contested. Premature old age indeed is described as the climax of a series of excesses and of sins of omission. The treatment recommended to ensure rejuvenation aims at establishing a new functional equilibrium; for this purpose the extensive auto-intoxication present in premature old age; a form of intoxication started to be much commoner than is generally believed, is that due to taking medicines.

*What is Man?* By J. Arthur Thomson, M.A., LL.D. London: Methuen & Co., 1923. (Cr. 8vo, pp. 241, 6s. 6d. net.)

*South*. By Dr. Jean Frommann, with a preface by Jean Frommann. Translated from the French edition by Elaine A. Wood. Sixth edition. London: John Bale, Son, and Dancelsen, 1923. (Cr. 8vo, pp. viii + 123, 7s. 6d. net, postage inland 6d.)

Royal Society of Medicine participated, was held was taken by Mr. H. J. BANKS-DAVIS (President of section of Laryngology), who mentioned that although discussion was under the auspices of the Society, the it originated with the Ministry of Health in con- a with the official inquiry into the subject now

### *Laryngology.*

P. WATSON-WILLIAMS said that the quest for cocaine substitutes had been fruitful, but while some were of great and had already displaced cocaine in certain departments the majority were of quite ephemeral repute. The anaesthetic efficiency and safety in clinical dosage, but also be devoid of temptation in the case of the habit should have prejudiced most unfairly the use of a valuable anaesthetic. Sir William Willcox recently that the claim for any new drug that it not lead to "addiction habit" needed very careful ation before it could be accepted, and Dr. Watson- doubted whether there was sufficient evidence in of any cocaine substitute to show that it was free s risk. He felt, however, that the "addict risk" ed. The comparative clinical value of cocaine sub- turned largely on the purpose for which an anaes- thic required, and they must be judged, first according method by which anaesthesia was to be induced, and, second place, according to the region to be anaes- . Apart from the general questions involved, he His personal experience of eucaïne and butyn icted to their use by surface absorption, and he that butyn was less efficient than cocaine whilst ally or even more toxic. These, and indeed all n substitutes, had the serious defect that adrena- be added if vascular constriction was desired, i gave rise to prolonged and undesirable after- , therefore avoided adrenaline wherever possible, ed his use of eucaïne and butyn to such cases as ustachian catheterization unless ischaemia of was desired. He had suggested to his son (Mr. -Williams) a research on the toxicity of cocaine itutes, and the results appeared in the *BRITISH JOURNAL* of December 1st (p. 1018). The mind ision should be disabused of the idea that these itutes were safe; they were not safe unless the age were very carefully estimated. He men- ures of fatal cases published in the preliminary e American Committee on toxicity of local ncluded in the paper just quoted), and seeing as used in far greater frequency than any of s, and that many of the substitutes indeed neral use at all, he urged that these fatalities ey must not be regarded as safe. After using 1886 in rhinological work, he could not recall ; results when swallowing was precluded and of a strong solution used: when again it was at cocaine was used in every clinic and that atients must be having applications on any of accidents, and the paucity of the cases of h could be traced to these administrations . The risk was further reduced by the pre- ultaneous use of adrenaline and the alka- ine solutions which enabled smaller quan- Moreover, many of the accidents reported ne were really due to carelessness. He had efficient substitute for it as an intranasal tic.

view they had to consider (1) whether any drug or combination of drugs was equal or superior to cocaine in degree of anaesthesia given and the rapidity with which that anaesthesia was obtained; (2) what amount of irritation followed the use of the various local anaesthetics; (3) the liability to cause desquamation of the corneal epithelium. Toxicity, stability, and other questions also entered into the consideration. From the point of view of infiltration anaesthesia, he thought it might be admitted that novocain in 1 or 2 per cent. solutions could properly take the place of cocaine. Cocaine had power to stimulate the sympathetic nerves, and it had been suggested that this action might prove to be the test of its power to act as a stimulant of the central nervous system and therefore of its liability to become a drug of addiction—a very valuable test if it could be substantiated. He added that he had used stovaine both for inducing superficial anaesthesia and in cataract operations; he had found it unsatisfactory for the latter, and on two occasions had had to complete the operation with cocaine. Butyn anaesthesia he had found satisfactory, but the smarting was rather marked. He knew of no case of drug addiction resulting from clinical applications.

### *Dentistry.*

Mr. F. N. DOUBLEDAY referred to a questionnaire sent out by the British Dental Association, the result of which was that 1,912 dentists replied that they considered cocaine, as distinct from its substitutes, essential in dental practice, while 410 replied that they did not: he ranged himself with the latter. He believed that novocain was a most efficient substitute, and he described its value in dental operations. Most of the other substitutes gave similar results, but with less certainty, and with more marked after-effects. A few patients showed a marked susceptibility to novocain, but these cases were very rare, and he had used novocain widely at Guy's Hospital without any ill effects for patients, many of whom were in poor condition, and some suffering from disease.

### *Anaesthetics.*

Dr. JOSEPH BLOMFIELD said that the use of these drugs in his practice as an anaesthetist was entirely confined to injection, and he had had no experience of their surface applications. He had entirely abandoned the use of cocaine, and he believed most of his fellow anaesthetists had. Novocain in strengths up to 2 per cent. was chiefly used for injections into the sacral cavity. In such injections it was apparently harmless, though occasionally, when large amounts were used, the patient appeared to have something like generalized convulsions, affecting almost every muscle of the body, but this condition passed off. With regard to stovaine, since it had been learned that the chief danger with this drug was the fall of blood pressure which it induced, measures were taken to counteract this, and the drug was used safely.

### *Otology.*

Sir WILLIAM MILLIGAN confined his remarks to the action of butyn. Otological work did not permit of the same range of utility for the employment of a local anaesthetic as did laryngological, rhinological, or dental work, owing chiefly to the configuration of the organ of hearing and its position. Such local anaesthetics as eucaïne, stovaine, and novocain all had their champions, but so far as his experience went cocaine had very easily held the field. The advent of any new anaesthetic called for very critical examination from several points of view, first of all as to whether it was of equal or superior effectiveness to the anaesthetic already in use, whether it was reliable, whether it possessed toxic properties, and, if so, how these might be applied to the tissues in fluid, or solid form, by subcutaneous injection or by means of infiltration, but it must be allowed to come into intimate contact with the

## MAKERS OF SCIENCE.

are a lucidly set forth by Mr. J. C. Steinger. In a discussion of the causation of catarrh, A. W. Ormond leads up to the conclusion that no agents, such as an enzyme, are able from the failure of the protective function of the capsule to reach the hydroxy to the lens fibres. The number contains the

Dr. Ivor B. Hall traces the progress of physical mathematical science from the earliest times to Einstein's theory of relativity. Dr. C. Singer, in an interesting introduction, says that in recent years the history of science, which still needs expansion and completion, has begun to be displaced not entirely by the place of biology, but by the history of science and mathematics. He points out, as he points out, that the history of science and mathematics, which demands greater knowledge from its students, the other the biographical method, which is probably the best and most attractive.

pioneers named have been chosen rather from their ability as poets on which the scientific eventuality of their times than from any superiority over their contemporaries. William Gilbert (1544-1603), the father of modern physics, and Galileo Galilei of Pisa, the founder of modern physics, were the two outstanding pioneers in the revolution of the scientific method in the sixteenth century. Gilbert was President of the Royal College of Physicians, 1600 and a Court physician, dying in the same year as Queen Elizabeth, as if, in Thomas Fuller's words, such this loyalty to the Queen, he was unwilling to survive the middle of the seventeenth century saw the final throw of the Aristotelian tradition under Sir Isaac Newton's leadership. The notice of Robert Boyle, who it is, became a life-long sturtever by imitation early in his life, contains an account of the origin of the Royal Society by Boyle, as Boyle called the first members. He is said to have feared death only because he would then know things and so no longer have the delight of making experiments. The remainder of this pleasantly written and admirably illustrated handbook deals mainly with magnetism and electricity as exemplified in the work of Ampere, Dary, Faraday, Kelvin, and Einstein.

THE ROMANCE OF MEDICAL MISSIONS.

There has been published under its modest prosaic title, in various parts of the world—Africa, India, and China—the book can be read through leisurely in an afternoon but the reader may be warned that whoever begins to want to finish it.

Perhaps the title, *Medical Practice in Africa and East*, may have been intended to prevent suspicion the contributors, being missionaries as well as doctors, might be foisting on the public something goody-goody. The book is all good, but none of it is good, whilst a high moral tone, and the sympathetic introduction of Mr. Stephen Page, enhance its value. In brief it gives a vivid picture of medical practice among native populations in remote areas where consultation or qualified assistance is unobtainable, and where equipment is elementary or incomplete, so that initiative and improvisation are necessary.

and stress is laid on the value of light and electricity in the cure. Treatment by endocrine extracts or operations on the thymus of Steinhilber and Voronoff are not discussed in this volume. The translation suffers from want of supervision from someone conversant with medical terms, as is shown by the sentence about the heart: " , , its rhythm is distracted by the toxicated nervous centres and considerably intervened by the dilatation of the tormented and swollen arteries point."

THE concluding quarterly number of this year's volume of the *Guy's Hospital Reports* has a sympathetic notice of the late Sir George Savage by Dr. R. Percy Smith, which is reprinted from the October number of the *Journal of Mental Science* for 1921; it is illustrated by two portraits of this genial psychiatrist, who for thirty years found one of the joys of his life in teaching the students of Guy's Hospital. Of the two papers dealing with pneumonia and syphilis, that by Drs. G. H. Hunt and A. A. Osman shows that enucleation of the tonsils is not a certain preventative of a recurrent rheumatism; indeed, in patients submitted to operation. Many factors must be

taken into account in considering tonsillitis in rheumatic children, and it would seem quite unjustifiable to perform this operation on rheumatic children whose tonsils and lymphatic glands appear to be healthy. The writers also conclude that, although the tonsils may be the primary focus of entry in the first attack, the virus may persist in some other part of the body, such as the heart. From observations extending over four years of tonsillar infection in cardio-vascular diseases Dr. H. J. Starling of Norwich is convinced that the tonsils are the portal and focus of rheumatic infection, that the presence of enlarged glands under the jaw is a more certain proof of tonsillar infections than the appearance of the tonsils, and that enucleation of the tonsils, which should be absolutely completed, as a small remnant may be as effective as the whole tonsil, is a most valuable preventive measure. But he says that, as rheumatic infection is largely influenced by conditions of climate and soil, it is not surprising that a child on returning to the environment of the original rheumatic attack should relapse in spite of tonsillectomy. It is suggested that acute rheumatism and chorea are due to the spread of tonsillar infection by the blood stream, and that rheumatoid arthritis is the result of intestinal infection of tonsillar origin. In a thoughtful paper on cardiac murmurs and Sydney Hospital, describes a case of auricular fibrillation with a presystolic murmur, and states his opinion that in thoracic aneurysm no murmur of any kind is audible unless the aortic valves are incompetent. He argues that in auricular fibrillation the striated muscular tissue of the article is completely paralyzed, and that then the unstrip-

Dr. J. A. Knott, writing, under the inspiration of Dr. Hirsch, on the gastric germicidal barrier, brings forward experiments to prove that clinical conditions arising from infection and absorption of their toxins may often be due to deficiency, temporary or permanent, of the hydrochloric acid in the gastric secretion, and that this should be remedied by the oral administration of this acid, alone and not mixed with proteins, such as those in milk, which immediately remove some or all of its germicidal power.

An article "On some cases from 'Clinical'" is preceded by a note on the history of these wards, to which specially interesting medical cases have long been sent; among the

mucosa of the middle-ear cleft. Its range of utility, therefore, was largely narrowed down to those middle-ear conditions in which the mucosa was exposed either as a result of disease or artificial perforation of the membrana tympani. Applied locally to the mucosa of the middle ear or to the Eustachian orifice, it would be found to produce sufficient anaesthesia within one or two minutes to arrest pain following upon the application of certain caustics, though not of all, but it required repetition before a quite satisfactory and profound anaesthesia resulted. He had had no experience of its toxic properties as applied locally, and he had had no patient who was in any way inconvenienced by its use. In painful affections of the external ear or the external auditory meatus, it could not, applied locally, be of much service in consequence of the nature of the integument. Injected subcutaneously, however, it produced anaesthesia sufficient to permit the opening of a furuncle, though he did not recommend it for this purpose. He had not yet attempted to open the mastoid cells under butyn anaesthesia. In oral work, butyn did not appear on balance to offer any advantages as compared with cocaine. Its tendency to produce hyperaemia seriously prejudiced the many excellent properties the drug otherwise possessed. At the same time, his experience in oral work showed butyn to be more rapid in its action than cocaine, and its potency to be nearly twice that of the older anaesthetic. It could be used quite effectively in lower concentrations than other synthetic anaesthetics. In the early days of his practice he found patients who presented symptoms of cocaine poisoning, but these mishaps had long since passed away, and he had no doubt that they were due to faulty technique. He had had the unfortunate experience of seeing two patients contract the cocaine habit, one a barrister, who constantly used a nasal spray and developed such mental symptoms as necessitated his confinement, though he was now quite well; and the other, a medical man who, as a result of vascular changes, had a severe hemiplegia, which proved fatal.

#### General Discussion.

Mr. ERIC WATSON-WILLIAMS repeated the statement (given in his paper in this JOURNAL) with regard to the report of the proprietors of butyn on five deaths following clinical application of that drug, but he added that a more recent letter from the proprietors stated that butyn in 1 per cent. solution had been used in over a million extraction cases by dentists in the United States, without a single untoward result. It happened sometimes that trouble was attributed to the anaesthetic when actually the cause was something quite different. One of the most amusing examples was a case seriously recorded in a medical journal (which he named) in this country in which a medical man, having toothache, applied cocaine to his gums, and afterwards, beginning to feel queer, suspected cocaine poisoning, and so took an antidote in the shape of whisky, half a glassful every half-hour. He had a most restless and excited night, but on the following day, although he felt very much out of sorts, all symptoms of cocaine poisoning had disappeared. On the general question of deaths reported following the use of local anaesthetics, especially for tonsillectomy, Mr. Watson-Williams wished to emphasize the foolishness of drawing conclusions from any but complete case reports. In a number of reports recently examined by him no mention was made, for example, of swabbing or spraying the fauces before injecting the tonsils or faucial pillars—an almost universal practice. If strong solutions were used on swabs absorption here might be very rapid, for 5½ minims of a 20 per cent. solution contained 1 grain of cocaine; to give the dose only of the drug injected might be very misleading, and cause the quite possibly false impression that small fractions of a grain of cocaine, novocain, or the like could cause death.

Mr. S. F. ST. J. STEADMAN, in various dental operations, had usually taken a 2 per cent. solution of novocain, and was fairly satisfied with this drug. On one or two occasions he had failed to obtain satisfactory anaesthesia, and in one man not one of five injections was satisfactory. These cases of failure were in ex-service men who had suffered from shell-shock. On using a butyn solution also

he had found in one case no anaesthesia at all and in two other cases very unsatisfactory anaesthesia. By using novocain in freshly prepared distilled water he had abolished after-pain.

Dr. G. WILLIAM HILL was in substantial agreement with Dr. P. Watson-Williams and Sir William Milligan in their reference to the fact that cocaine in experienced hands was not a dangerous drug. At the Portsmouth meeting of the British Medical Association he had read a paper on butyn, but since that paper was written events had moved very rapidly, and it appeared that butyn, although previously thought to be safe, was in fact far from being so. In his own experience, however, he had never found the slightest palpitation nor poisonous effect resulting, and his own observations went to show that butyn was very non-toxic compared with cocaine. At the same time, he damned butyn with faint praise because he found it a very inconvenient drug to use on account of the fact that it was not ischaemic, and that when adrenaline was added this acted as an irritant, so that patients complained not merely of coryza but also of very unpleasant sensations. Further, he found that it was uncertain in its action. Sometimes it failed to anaesthetize altogether, and for this reason principally he felt that it was not worthy of the confidence given to cocaine. While it was true that butyn in his hands had given rise to no toxic symptoms, it was not until his seventeenth observation that he discovered the uncertainty of its action, so that a more extended series of observations might have yielded a toxic case. He had been asked by the Ministry of Health Committee to try stovaine, and his experience was that it was not free from toxic dangers, or at least that it caused toxic symptoms. Altogether he was inclined to think that nothing better than cocaine was at present available.

Dr. ALBERT GRAY dealt with the effect of certain of the anaesthetics locally on the membrana tympani. He had found eucaïne, stovaine, and novocain all very much inferior to cocaine so far as the production of anaesthesia of the unbroken membrane was concerned. He had never had any patient who became addicted to the cocaine habit. The nearest he had was a patient in whose case he had been employing watery solutions in the nose, and who began to like this treatment. Since he had used ointments, which were very gradually absorbed, instead of watery solutions, he had had no anxiety on this score.

The CHAIRMAN recalled a case in his early days in which a man—the head draughtsman in an architect's office—became addicted to cocaine as a result of cocaine being used to spray his throat. He came up almost daily with fits of coughing which necessitated the use of a spray if the throat was to be inspected at all. Later he had an accident, which confined him to hospital and made it impossible for him to continue his visits, and he admitted that he had been in the habit of coming, not because of the condition of his throat, but because he wanted the spray, and he was able in the exaltation which ensued to go back to his office and make the most splendid drawings. The circumstances of his accident cured him of the approaching habit.

Mr. T. B. LAYTON gathered from the ophthalmologists that from their point of view the important consideration, next to its anaesthetic property, was the irritant effect of the drug. This was not of the same importance in the nose and throat. It was not possible to compare the surface applications of the laryngologist with the ophthalmic applications for work on the cornea or conjunctiva. What the laryngologist or rhinologist would call a surface application was really comparable with the intraocular operations of the ophthalmologist. With regard to butyn, he had noted from pamphlets supplied by the manufacturers that it was twice as toxic as cocaine; therefore he made it up in half the strength at which he was accustomed to use the cocaine. He had never seen any untoward effect, but he would approach it with more anxiety after having listened to Mr. Eric Watson-Williams. The speaker was unable to distinguish between the toxic symptoms of cocaine and its substitutes and the symptoms obtained in mental states such as fear. He was not at all sure that the latter did not explain many of the symptoms attributed to the drug.

11 *Elementary Hygiene*. By Bilhari Lal Bhattacharya, M.Sc., F.Z.S., and Prem Nath Sengupta, M.B., B.S. London, Calcutta, New York: Longmans, Green, and Co. [1923]. (Cr. 2nd p., 41; 11 figs. rec., 2, 64.)

12 *Operative Dental Surgery*. By T. R. Partridge, M.R.C.S., L.R.C.P., I.D.S. Second edition. London: Edward Arnold and Co. 1923. (Demy 8vo, pp. 342; numerous illustrations, 21s. net.)

More than one that evening had stated that he used to have these results, but had them no longer, and the speaker suggested that this might be because the technique of application had been better learned, and therefore the surgeon no longer suggested to his patients the symptoms which he himself feared might arise. It was very easy to get toxic symptoms by simply suggesting those symptoms to the patient. One point with regard to adrenaline: there was more danger of reactionary haemorrhage in local than in general anaesthesia, and if one went on adding adrenaline the danger of that reactionary haemorrhage was increased.

Dr. J. B. HORGAN had tried alypin in 10 per cent. solution for surface application on the nose, and had used it about twenty times. It proved to be much more toxic in its action, strength for strength, than cocaine, and he gave it up on that account. He mentioned that 10 per cent. calcium chloride injected intravenously was a rapid and efficient antidote of the severe types of cocaine poisoning.

Dr. A. S. GREEN of Lincoln related his experience as a patient on whom both cocaine and butyn had been used. While the anaesthetic action of cocaine had been very good, it had disagreeable after-effects for a time. Butyn was more satisfactory in this respect, and the anaesthesia was perfect. The sensation in the nose, where the operation took place, was quite different in the case of butyn from what it was with cocaine; with the former the nose felt as if it were frozen.

Mr. SYDNEY SCOTT said that at St. Bartholomew's Hospital twenty-five years ago they were taught that it was exceedingly dangerous to spray the nose with cocaine. The fault was that the old sprays at one squeeze of the bulb would eject a large quantity, some of which might be swallowed. It was very necessary to avoid any swallowing.

Mr. HERBERT TILLEY could only speak of novocain among the substitutes, but of this he had had a fairly large experience. He had used it frequently in resection of the nasal septum and operations on the antrum, and had found it extremely efficient: he had never seen it give rise to dangerous or even to uncomfortable symptoms. He felt, however, that there was no drug which so effectively combined the production of anaesthesia with contraction and retraction of the tissue as cocaine itself. He believed that cocaine might be extremely toxic if used as an injection, but large surface applications seemed quite innocent, perhaps because of some biochemical action of the skin or mucous membrane which, so to speak, filtered out the toxicity.

Dr. P. WATSON-WILLIAMS, in a brief reply on the discussion, said that the profession stood in some danger of getting a wrong mental attitude with regard to cocaine. If a better or more efficient substitute could be obtained it should be adopted, but it seemed a pity that it should now be black-listed so far as its proper clinical use was concerned, because of its social abuse in the past. He thought it ought to stand on a par with any substitute which was brought forward. It was unscientific to start out with the idea that cocaine must be tabooed when such taboo meant the acceptance of something clinically inferior.

## ANAESTHETIC PRACTICE.

A MEETING of the Section of Anaesthetics of the Royal Society of Medicine was held under the presidency of Dr. A. L. FLEMING at the Medical Institute, Edmund Street, Birmingham, on Saturday, December 1st. The time at the disposal of the Section was cut short by the lateness of the arrival of the train bringing the London members.

Dr. K. B. PINSON opened the proceedings with a paper on the condensation of dimethyl ether, and its use as an anaesthetic. He said that when he promised to read the paper his experiments were not yet completed; owing to a succession of accidents they were still unfinished, and he was not able personally to give the drug as an anaesthetic before he read his communication. His attention had been called to it when reading Gwathmey's book by a statement that W. B. Richardson had administered it in some twenty-seven cases and was favourably impressed. Accordingly Dr. Pinson had attempted to prepare and condense the drug with the object of administering it as

an anaesthetic. The ideal anaesthetic should be easy and quick in induction, pleasant to take, non-irritating, easily controlled, and quickly eliminated. A gas was more likely to possess these attributes than a fluid. Dimethyl ether at normal pressure and temperature was a gas. Its physical properties were not well known. It might act on metals and on oils and might therefore be difficult to condense, as it might act on the apparatus used for compression. In his experiments he found that it boiled at  $-24^{\circ}\text{C}$ ., and that at  $100^{\circ}\text{C}$ . it exerted a pressure of 97 lb. to the square inch, and could thus be safely stored in cylinders. He had only got so far in his experiments when the apparatus used exploded and the small quantity of the gas he had been able to procure was totally lost. So far he had not been able to obtain a further supply. He had, however, found that the gas condensed into a thin, limpid, mobile liquid with a slightly ethereal pleasant odour. He concluded by demonstrating the apparatus with which he had conducted his experiments, and explaining the difficulties met with.

Mr. LEONARD GAMGEE, in his paper entitled "A surgeon's thoughts on anaesthesia," stressed the necessity for the complete co-operation of surgeon and anaesthetist, especially in the more complicated operations, such as those on the thyroid gland. At such operations everything in the theatre, including the surgeon and his assistants, should be ready for the operation before the anaesthesia was even started, so that if any respiratory obstruction occurred the surgeon could at once relieve this by rapidly cutting through the superficial muscular layers. Later on, when pulling on the lobe of the gland to free it from the trachea, he should be prepared to let it fall back in its bed should obstruction arise. A surgeon should never dilate the sphincter ani without informing the anaesthetist that he was about to do so, as there was risk of collapse should this be done with the patient too lightly anaesthetized. Mr. Gamgee quoted in this connexion a death resulting from the division of the corpora cavernosa when the patient was in a state of light narcosis during an operation for amputation of the penis. In this case the surgeon could not be freed from blame as he had not warned the anaesthetist of his intention to divide the organs. Lightness of anaesthesia had distinct dangers, and added to the risk of operation and after-shock. There were also other risks. One of these was an inefficient operation, and another, forcible expiratory breathing, especially under ether, of uncertain origin, but possibly due to the surgeon starting too soon. Another possible cause was that ether had been given too long, and this was noticeable in operations upon the upper abdomen. Hampered by this type of breathing, the operator should inform the anaesthetist and give him time to get a deeper anaesthesia. In regard to pre-operative drugging, the tendency nowadays was to give too many drugs before operation.

Respiration was depressed after scopolamine and morphine, sometimes even to the extent of producing a sort of Cheyne-Stokes breathing. While morphine alone was less objectionable, cyanosis and shallow breathing were common sequels; moreover, the patient was apt to remain unconscious longer than was desirable. Morphine should never be given without the knowledge and consent of the surgeon. Atropine came under a different category and could be left to the discretion of the anaesthetist. Ether was the safest anaesthetic, but had after-effects often undesirable. It should not be given for more than half an hour. The complications were due to a lowering of resistance and possibly also to direct inhalation of septic organisms as the result of the deep expiratory breathing already referred to. Gas and oxygen, while valuable, nearly always required reinforcement in abdominal cases, and, except in expert hands, were not as safe as ether. Why was it that the Vernon-Harcourt inhaler was not more used? By it chloroform could be given safely, and with comfort to the surgeon also. The mask and drop-bottle, so far as chloroform was concerned, were a danger in the hands of the inexperienced. Plenty of chloroform and plenty of air was an excellent motto, but one that could not be followed when using a mask covered with over so many layers of material. A folded

the other the annual report of the National Institute for the Blind. The Advisory Committee consists of a chairman and vice-chairman appointed by the Minister of Health, representatives of the County Councils Association, of the London County Council, of the Associations of Municipal Corporations and of Poor Law Unions, and of voluntary agencies for the blind. It is a really working committee which collects information on the doings of the statutory authorities, advises them on their duties, seeks to co-ordinate effort, and reports to the Minister; its expenditure for the year was £192, including the cost of the publication of its report.

Progress is being made in the application of the provisions of the Blind Persons Act, and the number of pensioners rose from 9,107 to 9,921. These pensions are a boon to the aged blind, and release voluntary funds for other purposes; but some hardships have arisen owing to local authorities withdrawing aid previously given to aged blind, so that on balance they were worse off. It is hoped that this may be remedied. It had been feared that the introduction of rate-aided services might adversely affect voluntary contributions to funds for the blind, but so far this has not happened; since the passing of the Act new voluntary agencies have been formed and existing ones extended. This may be due partly to the wise method of the Ministry and the local authorities in acting so far as possible through the existing voluntary agencies. It is considered that co-operation among superintendents of workshops for the blind would lead to economy, and that the uniform system of account keeping prescribed by the Ministry should be adopted; a uniform system of costing is advocated. The necessity for these measures is shown by the inequality of the maintenance charges at various institutions.

In Germany there are 33,000 blind (on a stricter definition) as compared with 35,000 in England and Wales; 5,000 in Germany owe their blindness to the war, as against 1,600 here. Many of the blind are in residential workshops in Germany, a provision rare here. The work done is almost identical, but in Germany some 450 are employed in ordinary factories or workshops. Attempts are being made to introduce the more skilled of the blind into ordinary workshops here also, especially those whose blindness is due to industrial accidents. In France the majority of the blind workers are home workers; only 600 are in institutions for the blind, and 21 in ordinary factories. There are in several areas local centres that buy and sell for the home workers. The blind beggar still exists, despite all the provision made for him. Some cities have suppressed the blind made for him. He has generally fled to the next city. The need for general action is pointed out. The report adds: "We venture to suggest that the public have the matter very largely in their own hands, as by their generosity to the blind of their own hands, as by their generosity to the blind of voluntary agencies to persuade blind beggars to accept the provision made for the blind generally rather than appeal for alms in the street."

The evil influence of the easy gains of the lazy and idle upon the minds of the industrious renders indiscriminate charity reprehensible. Attention is drawn to the necessity for the proper examination of those claiming to be blind before they are admitted into workshops for the blind.

It is believed that there are in workshops and elsewhere a number of persons in respect of whom grant is being paid by the Ministry who are not properly blind within the definition of the Regulations governing grants in aid of the welfare of the blind and the Blind Persons Act, and it has been suggested to us that the fourth Annual Report of the Advisory Committee on the Welfare of the Blind, published by the Blind, Annual Report, 1922-23. Headquarters, 22, Great Portland Street, London, W.1.

THE second International Congress of Otolaryngology will be held in Rome from April 23rd to the 26th, 1924, under the presidency of Professor Alessandro, when the following subjects will be discussed: (1) Renal innervation, introduced by Ambard of Strasbourg and Soja of Pavia. (2) Vascular innervation of the larynx, introduced by Rosing and Wiedemann of Copenhagen. (3) Remote results of operation for renal calculus, introduced by Bronchmann of Amsterdam. (4) Recent progress in otology: (a) pathogenesis of otitis media, and (b) otitis media of children, introduced by Sir John Thomson-Walker. (c) Vestibular malacoplasm, introduced by Barrington of London. Further information can be obtained from the secretary, Dr. Bonamonte, 124, Via del Gracchi, Rome.

One part only of its many-sided work would be sufficient to justify its existence, and that is its publications department. The Institute is the general printer to the blind of these islands, and to some extent of countries outside our commonwealth. The eleven periodicals it issues in Braille and Moon type had a circulation of well over 200,000 in the past year. It printed also some 15,000 books and pamphlets in Braille and a third as many in Moon type. These books are issued at one-third cost to the blind of these islands, at half cost to the Dominions, and at cost to foreign countries. The loss on these publications, to be made up out of the general funds, was £8,169 for the year. Of no less importance is the manuscript department. The Institute has a staff of 150 voluntary workers, experts in transcribing Braille, who are prepared at short notice to produce in the type they can read any book required by the blind for advanced study. The demand for these transcripts is so great, especially from teachers of the blind, that the production of light literature has been stopped. Two thousand volumes are now in hand; they include some of the best of our literature in history, science, and law. 875 volumes were produced last year; one work transcribing thirty volumes.

Another fine piece of work done by the Institute was the establishment of the College for Blind Girls at Chorley Wood in 1921. The number of students therein is steadily increasing. Until the full complement of pupils is attained the cost is greater than can be met by the fees of pupils, so that the excess falls upon the general funds of the Institute. The King and Queen have approved and recognized the objects of the college by a generous donation. The college is a typical public school for girls, its standards are those of the best known of these schools. Its habitation and equipment are as perfect as well could be. The head mistress is a lady whose previous work as a Girl and Koedean is proof of her educational sufficiency. Medical men can do no greater service to this college and to those of their acquaintances or their charges who are blind or nearly blind than by putting the two into communication. The advantage to a blind girl of receiving a full education with a number of her comrades both in ability and disability cannot be overestimated.

The Sunshine Homes for Blind Babies are too well known to need more than a note that the northern home is now ready for occupation, and in it some thirty children will be received. Less conspicuous but no less necessary departments are those for the training of the blind in massage for the relief of the necessities blind, for after-care, and home teaching and the training of home teachers, and the provision of homes for some of the older blind. The statement of accounts shows that the expenditure for the year was just over £200,000; and there is here the only blot on the report, for a deficit of £43,268 has to be carried forward for the next year. Here is an opportunity to introduce grateful patients to a valuable mode of expression of their gratitude for their own recovery.

towel held at some distance from the face and freely sprinkled with chloroform was both safe and efficient. The danger signal was pallor of the face, and when this occurred no more chloroform should be given. The best ether apparatus was the Clover machine or its modification by Hewitt. So-called open ether was not open ether at all, but a smothering of the patient accompanied by partial narcosis of the anaesthetist and the whole of the surgical staff, resulting from the amount of ether distributed to the surrounding air. Mr. Gamgee then touched on the psychological element in the taking of anaesthetics. Seldom was trouble experienced in anaesthetizing acute cases; such patients were only too pleased to inhale the drugs in search of relief from pain. It was otherwise when dealing with interval cases of appendicitis, hernias, and operations of that kind; trouble was often experienced in such cases. Theatres were often kept a great deal too hot. By taking a patient from a warm theatre into a cold corridor, down a draughty lift, into a ward in which the breezes were apt to blow from open windows, post-operative bronchitis was more than likely to follow. This was rare in nursing homes and very rare in private houses after operation. Many of the difficulties of the anaesthetist could be put to the blame of the surgeon, and many could be put to the blame of both. The anaesthetist should get the patient sufficiently under for the comfort of the surgeon, and the surgeon should tell the anaesthetist all that he knew concerning the patient, as in many operations the anaesthetist really ran the greater risks. The surgeon should always work with the anaesthetist, curb his own ardour, and be prepared to wait.

Dr. A. L. FLEMING remarked that chloroform was not taught to the same extent as ether administration, and considered this the direct result of the strictures of coroners when holding inquests on fatalities. He advocated the provision of recovery wards, but these should not be made too attractive or they would be seized by the surgeon, always voracious for empty beds. Such wards, therefore, should be earmarked solely for the purpose for which they were provided; they should be near the theatre to obviate the use of lifts, and should be specially staffed.

Mr. W. BILLINGTON said that anaesthetics were a necessary evil, but if there was danger of explosion, as seemed to be the case with Dr. Pinson's anaesthetic, the evil was increased. As regards scopolamine and morphine, there was danger of acetonæmia following their use. They should never be administered if a psychological disturbance were present. He preferred to administer morphine earlier than was the custom so that some of its immediate effects had passed off before the anaesthetic was administered. He preferred the preparation omnopon to the usual morphine salts. More rapid elimination could be secured by giving the patient large doses of fluids before the anaesthetic was given, and plenty of fluid afterwards. The collapse that sometimes occurred early in operations such as hernia and interval appendicitis operations could be remedied by the prompt use of pituitrin. He then described the method of giving anaesthetics practised at the Mayo Clinic.

Professor HODDAY stated that, contrary to the usual statements, dogs were ideal patients for the administration of chloroform, provided this was given by means of a suitable apparatus. He showed a portable apparatus which was, he said, both cheap and efficient.

Dr. WALTER JORDAN said that by an accident he was still an anaesthetist although he had gone over to the physicians many years ago. He had forgotten to resign an appointment at the Orthopaedic Hospital, with the result that he had given chloroform there in over 11,200 cases. He had never had a case of acetonæmia, pneumonia had never been seen by him after administration, and death had occurred only once, and in that case the patient was over 70 years of age.

As the time available had now practically come to an end, Dr. Kirkby Thomas demonstrated a new intratracheal apparatus for the administration of ether and chloroform, after which the members moved to the Union Club to enjoy the hospitality of the Birmingham anaesthetists.

## METHODS OF BLOOD CULTURE.

SIR CLIFFORD ALLBUTT occupied the chair at the meeting of the Section of Comparative Medicine of the Royal Society of Medicine held on November 28th, when a paper was read by Dr. S. G. BILLINGTON on some unusual methods of culturing the blood, with special reference to distemper. Dr. Billington first dealt with the development of certain "coccoid bodies" which made their appearance when small quantities of blood were incubated for five to thirty minutes at 60° C. in a medium consisting of distilled water containing 0.5 per cent. ammonium carbonate or neutral lemon broth containing 0.05 per cent. ammonium citrate; emulsions of these "coccoid bodies" had been used as therapeutic agents in infective disease, and it was claimed that they exerted some antibacterial effect. Similar media had been used for culturing bacteria from the blood, and by the use of a special technique successful cultures were obtained from a large number of cases in three to ten days. In order to obtain positive cultures there must be the correct proportion of blood to medium, the reaction must be neutral, and the serum or plasma concentration must be correct. In order to check the cultural results obtained Dr. Billington determined to investigate a specific disease of unknown cause and selected distemper, for if the cultural methods described were sound they should yield a constant organism. An outbreak of distemper at the North Stafford kennels provided him with material for twenty-five blood cultures, and fifteen other blood cultures were obtained from sporadic cases of distemper in the Wolverhampton area. The most constant organism obtained was a pleomorphic Gram-negative bacillus which grew best at about 25° C. and failed to grow at body temperature. The 25 blood cultures from the foxhounds yielded 22 positives and the 15 cultures from the Wolverhampton dogs 13 positives. Other bacteria were frequently present with this bacillus. The organism was described as being diphtheroid both in form and grouping, non-motile, and not producing acid or gas in glucose, lactose, saccharose, maltose, dulcitol, or mannitol. Dr. Billington shared the common belief that the actual causal organism of distemper was a filtrable virus, but he expressed the opinion that these associated bacilli might be utilized to type the disease and to provide prophylactic and therapeutic remedies. He reported some very favourable results obtained by employing an agglutinated haemo-vaccine prepared from the "coccoid body" emulsions, and demonstrated slides and films of the "coccoid bodies" from blood and the bacteria obtained by special cultural technique.

Major CHAMBERS and Mr. TRIGGER both expressed themselves as having been very favourably impressed by the clinical results obtained with Dr. Billington's haemo-vaccine.

Dr. DOUGLAS declared that it was difficult to criticize Dr. Billington's work without having attempted to repeat his experiments, but he stated that it seemed extraordinary that these "coccoid bodies" should develop into bacteria, for they looked to him like debris of organic matter. He remarked that very little information had been given by Dr. Billington of the nature of these bacteria when obtained in pure culture. If the blood of a dog suffering from distemper were taken whilst the temperature was rising and injected into a susceptible puppy distemper could be induced in this second animal. Also Ferry's bacillus had been frequently found in the blood, lungs, and trachea of dogs with distemper, and some workers had used this organism successfully for vaccine treatment. But Ferry's bacillus was not always present.

Sir WILLIAM LEISHMAN pointed to the many pitfalls which must be avoided before concluding that one organism evolved into another; merely morphological records were liable to be unsatisfactory. Many of the films appeared to him like mixed cultures, but the clinical results reported seemed promising.

Dr. ROWLANDS remarked that bacteria were often found in the blood in other diseases, such as swine fever, where they had no causal relationship to the disease. He was not persuaded that the "coccoid bodies" developed into bacteria.

## British Medical Journal.

SATURDAY, DECEMBER 15TH, 1923.

### THE ENDOWMENT OF MATURITY.

The new policy of the Royal Society may fairly be called the endowment of maturity; there is no reason to quarrel with it on that account. The Society exists, as William, Viscount Brouncker, its first president, said in accepting the charter granted by Charles II., "for improving natural knowledge," and no body more competent to decide how funds can best be applied to this end could be found than the Council of the Royal Society, upon which experts in all departments of science sit.

The policy was stated and explained by the President in the anniversary address, a report of which was published last week (p. 1113). The Society has been able for a good many years past to make certain annual payments from sums which it receives, chiefly from the Donation Fund and the Government grant. These have been used mainly to assist workers of promise in the early period of their career by providing the cost of apparatus and material, through research studentships, and by the Sorby Fellowship. In recent years the Society has come into the enjoyment of certain bequests and gifts—the Foulerton gift and bequest, yielding £5,050 a year, the Messel Fund, yielding £1,375, and the Xarow Fund, £5,450. Still more recently the death of Dr. Ludwig Mond's widow has liberated his bequest, which, it is anticipated, will yield an annual income of about £2,500. These new sources of income have placed upon the Society the responsibility of determining the best way of expending them. The policy it has now adopted is interesting from several points of view. It has decided that the income may best be spent in creating greater opportunities for experienced investigators of already proved first-rate capacity in research. Such men as a rule have hitherto occupied positions in universities or other institutions which require from them manifold duties. In almost all such institutions they must give up much of their time to teaching, and there are many other calls upon them of an administrative kind, and such calls are likely to increase rather than diminish. Thus they are taken away from research, the field in which their capacity has been proved. The Society has deliberately inverted the order of precedence of professional functions; it has placed its new professors in a position to regard research as their primary duty, and thereby has sought to recognize research as a definite profession, and to advance and to maintain the principle that the labourer is worthy of his hire no less when engaged in research than when he is employed in class instruction.

The need for a definite systematized policy was made the more urgent by the munificent gift of Sir Alfred Xarrow to the Society early this year. In his letter of last February announcing his gift Sir Alfred Xarrow said that he would prefer that the money should "be used to aid scientific workers by adequate payment, and by the supply of apparatus or other facilities, rather than to erect costly buildings, because large sums of money are sometimes spent on building in

without adequate endowment, and the investigators are embarrassed by financial anxieties." In arriving at its new policy the Council of the Society has been advised by a committee of which the donor is a member, so that there can be no doubt that it commends itself to him.

The first indication of the new policy was afforded just a year ago when Dr. E. H. Starling was appointed Foulerton Professor. Down to that time he had held the Foulerton chair of physiology in University College, London, and in that capacity his primary duty was to teach undergraduate students. The series of brilliant researches by which he has laid physiology and medicine under so heavy a debt were, strictly speaking, secondary. At the same time let us recognize that he could not have been so good a teacher of physiology had he not himself been, through all the years of his teaching, an active research worker. He is continuing to work in the Physiological Institute at University College, which was brought into existence mainly through his exertions, and will remain a permanent memorial of the trust his character and achievements have inspired. The two Xarow professorships—the one, Professor Fowler of the Royal College of Science, South Kensington, distinguished for his research in spectroscopy and astrophysics, and the other, Mr. G. I. Taylor of Cambridge, whose contributions to the mathematical theory of hydrodynamics and to the physics of crystals are recognized to be of the greatest originality and importance—will both, like Professor Starling, continue their researches in the laboratories of whose traditions, as the President said, their reputations are already a part.

The policy the Royal Society has adopted to guide its in the administration of the funds that have recently come under its control may therefore be regarded as presenting two closely related but slightly different aspects. In the first place it recognizes that certain professors should be relieved from the duty of teaching in order to devote themselves entirely to researches in which they have already gained distinction; in the second place it establishes the principle that a man of suitable temperament and abilities should be able to look upon pure research as a definite calling or profession in itself, which holds out to him a prospect that in the full maturity of his powers he may be placed in a position to give all his energies to following up the line of scientific inquiry in which he has already achieved success. It is a serious adaptation of Disraeli's rather cynical epigram that nothing succeeds like success.

### OESTRUS, OVULATION, AND MENSTRUATION.

In spite of an accumulation of observations and hypotheses, the very diversity of opinion expressed on the relationship of ovulation to menstruation problems our ignorance of this elusive problem. Its interest is not merely academic, nor is its practical importance appreciated only by breeders of stock; every scientific gynaecologist will admit the limitations of our knowledge concerning sterility in women, the functions of the corpus luteum, and the significance of menstrual, normal and abnormal. Clinical and post-mortem data have hitherto afforded conflicting evidence, and observations on animals have failed to elucidate the matter, inasmuch as the outstanding peculiarity of the human female finds no exact and certain counterpart in the lower species. The trend of recent work, which is summarized by G. W. Corner in an able

Dr. MERVYN GORDON asked if the "coccoid bodies" dissolved in 1 per cent. NaOH or 1 per cent. acetic acid. He had come across similar bodies when examining cultures on boiled blood media. These "coccoid bodies" were easily distinguished from the granules obtained in filtrates from influenza. With regard to the good results claimed from vaccine treatment he suggested that the filter-passing virus of distemper might be adsorbed on to the "coccoid bodies."

Professor F. HODDAY explained that he was not qualified to criticize the bacteriological details, but was deeply interested in the successful results of vaccine treatment, and thanked Dr. Billington for coming to London to impart his views. Dr. BARRATT suggested that the evolution of these coccoid bodies might be examined by dark-ground illumination.

Dr. BILLINGTON, in his reply, declared that many of the ordinary methods of performing blood culture were unsatisfactory; it was for this reason that he commenced his researches. He agreed that many of the points raised demanded further investigation. He did not claim that the bacillus isolated was the actual cause of distemper, but groups of bacteria were often associated together in disease—such as staphylococci with Pfeiffer's bacillus in influenza. In reply to Dr. Gordon he confessed he had not tried the effects of NaOH and acetic acid on the "coccoid bodies"; the size of these bodies varied with the concentration of calcium citrate and serum in the medium. The antibacterial properties of his vaccine might be due to the "coccoid bodies" or some hitherto unrecognized element.

## DISEASES OF CHILDREN.

A MEETING of the Section for the Study of Diseases of Children of the Royal Society of Medicine was held on November 23rd, with Mr. R. H. ANGLIN WHITELOCKE, President, in the chair, when Dr. J. D. ROLLESTON showed a specimen of hairball of the stomach.

The specimen was from a girl aged 15, an epileptic idiot, who suffered from vomiting and diarrhoea for a week before her death. A mass was found in the epigastrium which was thought to be the enlarged right lobe of the liver. On *post-mortem* examination the stomach was found to be filled with a collection of hair which formed a complete cast of that organ. On inquiry from the mother it was learned that the patient had been in the habit of eating her hair since she was a baby.

Dr. Rolleston reviewed the bibliography of this subject. He considered the x-ray appearance so distinctive—the hairball appearing a lighter area in the midst of the dark shadow of the bismuth—that a correct diagnosis should now be the rule instead of the exception. Mr. H. A. T. FAIRBANK showed a photograph of a hairball removed from the ileum of a girl aged 8 years, whose symptoms resembled those of partial obstruction.

Dr. W. E. ROBINSON showed a case of lymphangioma of the foot in a child aged 7 months. The foot was noticed to be growing larger, especially in the region of the metatarsal bones and terminal phalanges. The x rays, however, showed the bones to be perfectly normal. He asked for suggestions as to treatment. Mr. C. MAX PAGE suggested that a Syme's amputation appeared to be the most rational surgical treatment for this case. Mr. H. A. T. FAIRBANK suggested that the diagnosis should be that of hypertrophy of the foot, and agreed with Mr. Max Page as to treatment.

Dr. BENJAMIN showed, for Dr. Robert Hutchison, a case of precocious puberty.

The child, now aged 3½ years, began menstruation at the age of 17 months and had continued to do so at more or less regular intervals of one month up to the present date. The breasts were well formed and hair was present in the pubic region. Her weight and height were that of a child of 8 years. Mentally she was normal for her age, but had fits of bad temper. The carpal bones were ossified. He placed this case by a process of exclusion amongst those due to ovarian hypersecretion, although under an anaesthetic no definite evidence of this could be obtained.

Dr. C. WORSTER-DROUGHT showed a case of progressive neural muscular atrophy (peroneal or Charcot-Marie-Tooth type) in which the upper limbs were also affected.

The patient, aged 13, was one of a family of three, the other two not being affected. After the age of 2½ it was noticed that she turned her toes in and tended to fall down when she walked. During the past four years her feet had become more deformed

and the hands and arms have wasted considerably. Her present condition showed her to be thin and nervous, constantly wriggling her feet and legs. There was a tendency to bilateral main en griffe with marked wasting of the small muscles of the hand. The lower extremities showed pronounced talipes equino-varus of both feet with wasting of the peronei. The electrical reactions were given in detail.

Dr. Worster-Drought remarked on the difficulty in drawing a hard and fast line between certain neural atrophies, nuclear atrophies, and muscular dystrophies. Dr. NEILL HOBHOUSE gave the details of a similar but less marked case. The remarkable feature of his case was that one femur was smaller than the other.

Dr. NORMAN SCHUSTER and Dr. DONALD PATERSON showed a specimen from a case of paroxysmal tachycardia in an infant aged 9 weeks.

The specimen was the heart from a female child who had been admitted to the Infants' Hospital, Vincent Square, for blueness and shortness of breath from birth. The infant weighed 8 lb. When first seen it was wasted, feeble, and cyanosed, with a pulse of 200 to the minute. The heart seemed enlarged, as also was the liver. During her two days in hospital before death there occurred four different paroxysmal attacks lasting about ten minutes each, during which the infant had marked dyspnoea and cyanosis and was in obvious distress. The pulse at these periods became uncountable, afterwards falling as low as 140. Digitalis had no effect. On *post-mortem* examination a patent interventricular septum, patent foramen ovale, and patent ductus arteriosus were found. The pulmonary artery arose from the left ventricle and the aorta from the right ventricle. Microscopically the heart muscle showed degeneration with intercellular fibrosis.

Dr. GEORGE SUTHERLAND considered the case a very rare one, and cited a similar case of paroxysms of tachycardia which had been mistaken for petit mal. Dr. PARKES WEBER suggested that the cases reported in French literature under the heading of paroxysmal cyanosis were similar to this case. Dr. DONALD PATERSON, in reply, agreed that the reported cases were very few, but considered that attacks of blueness with rapid breathing were not uncommon in children with congenital heart disease. He wondered how many of these might turn out to be cases similar to the one reported were they as closely observed as this one had been. It was only by having the pulse charted hourly and specially taken during attacks that the condition could be diagnosed.

## RADIOGRAPHY OF THE FOETUS.

A MEETING of the Obstetric and Gynaecological Section of the Royal Society of Medicine was held on December 6th, with the President, Dr. CUTHBERT LOCKYER, in the chair.

Dr. T. I. CANDY read a paper of very great interest on radiography of the foetus *in utero*. He referred to various technical difficulties and explained how these had been overcome. He was now able to obtain a satisfactory picture after an exposure of not more than five seconds. It was difficult to believe that so short an exposure could possibly harm the mother or foetus. In certain cases pregnancy had been demonstrated at a very early stage. Positive evidence was naturally irrefutable, and he was even inclined to regard negative evidence as definite in cases of supposed pregnancy of six months' duration or more. Pneumoperitoneum had been practised in certain clinics abroad as a means of facilitating x-ray demonstrations, but he regarded this procedure as unjustifiable. The advantages of radiography were obvious. It had hitherto been used most frequently perhaps to diagnose multiple pregnancy; it was of further value in demonstrating the position and lie of the foetus, the date of the pregnancy, and the relative sizes of the foetal head and maternal pelvis in cases of doubt. It had been interesting to observe instances of rapid change of position of the foetus *in utero*; also to note the marked separation at the sacro-iliac joints quite early in pregnancy. The recent judgement in the French courts raised points of considerable medico-legal importance.

Dr. GEOFFREY FILDES exhibited reproductions of illustrative radiographs. In one case he had been able to detect the existence of twins *in utero* eleven weeks after the last menstrual period. He had attempted to localize the placenta, but was not as yet satisfied with his results; although, in a case of placenta praevia, the evidence appeared to be sufficiently definite.

It is therefore with very considerable interest that we note the results of certain definite experiments recently published by E. H. A. Marshall and W. A. Wood. Dr. Marshall is the author of that invaluable source of information *The Physiology of Reproduction*, and his work demands the greatest attention. It may be explained that the terminology originally proposed by Walter Heape is generally adopted. Thus the "anoestrus" is the period of sexual quiescence; the "prooestrus" is the period of coming on heat; and the "oestrus" is the period of desire. The periods of prooestrus and oestrus are commonly referred to together as the "heat" period. Heape regarded the prooestrus, and not the entire "heat" period, in animals as the physiological homologue of mensturation in women.

The experiments of Marshall and Wood consisted in the cauterization, shortly before a "heat" period fell due, of all Graafian follicles visible on the surface of the ovaries of bitches. This destruction of the follicles was found to abolish that particular period, and also to determine a prolonged anoestrus extending over the duration of two or more oestrous cycles. "Heat" subsequently reappeared, however, indicating the ultimate resumption of normal function and also that the uterus had not undergone atrophy. A mere pricking or cutting of the follicles without actual destruction failed to postpone the period of "heat." The authors conclude that prooestrus and oestrus are due to an internal secretion of the ovary produced by the follicles during the pre-insemination stage of development. This is distinct from the secretion responsible for uterine and mammary hypertrophy during pregnancy, which, with the majority of other observers, they assume to be produced by the corpus luteum. They also refer to an ovarian internal secretion which is responsible for maintaining the normal nutrition of the uterus; this they believe to be produced by the smaller follicles or by the interstitial cells. These conclusions in their entirety are possibly somewhat far-reaching on the basis of the actual experimental results, but the latter are obviously worthy of respect. Some further observations quoted in support of the theory are interesting if not conclusive. A condition of nymphomania has been described in cows and heifers in which the animals appear to remain continuously "on heat," and in which the larger Graafian follicles are found to have become cystic. Irradiation of the ovaries by x rays, which, as is well known, occasions temporary amenorrhoea, has been found to cause degeneration of the follicles, whereas the interstitial cells may even hypertrophy. The normal nutrition of the uterus of the rabbit has been preserved by ovarian grafts in which the follicle cells had degenerated, and, of the possible secretory elements, only the interstitial cells remained.

It is difficult to reconcile with various human observations the authors' contention that the corpus luteum

# CANCER AND HEREDITY.

The determination of the part played by heredity in presents peculiar difficulties. One is due to the fact the main incidence is at a time of life later than the reproductive period, so that the natural climatic and morbid strain, which usually occurs with hereditary factors, would be inoperative in the case of certain factors, it renders it very difficult to collect statistical information of the incidence of the disease in the families of cancerous patients, and this is increased by the rarity of autopsies and unsatisfactory systems of death certification. Similar difficulties to the study of the question in animals, but the part has been attacked from this side by Mand Sleye in an example, every pneumonic lung-ex are examined scopically. In this way more than 5,000 spontaneous tumours, mostly malignant, have been found, and the have been summarized by H. Gideon Wells in a recent on the influence of heredity on the occurrence of cancer. These experiments indicate that cancer in mice appears in most of the forms seen in man, and in far greater than had previously been supposed. Strains were produced in which, among many hundreds of individuals through twenty-five or thirty generations, not a single of tumour growth has been seen, while other strains been obtained with figures approaching 100 per cent. the incidence of cancer influenced by heredity, but at site and its character. For example, in some sarcoma is very common; in others it is found rarely never. In some strains any form of malignancy there have been more than a hundred primary tumours, while in all the other mice examined in laboratory not a single liver tumour has been found only two have been reported from other laboratories. Another strain has yielded a considerable number of the tests although not a single case has been reported from elsewhere. The resistance to cancer in these mice behaves in breeding, in Sleye's experiment like a typical Mendelian dominant character. The possibility behaves as a Mendelian recessive. In spite of Wells's assertion that human statistical evidence is

knownledge. the most dogmatic clinician of the deficiencies the utmost interest, and may even serve to internal secretions of the reproductive organs, which Dr. Marshall has recently published a logist, and the veterinary surgeon. A further between the gynaecologist, the comparative points serve to emphasize the need for collaboration.

 \* *Medical Press*, 81, 1017 and 1103, 1923.

In reply to Dr. EDEN, who suggested that x rays might be of value in following the course of the foetal head in labour, Dr. ROBERT KNOX said that he had already had an opportunity of witnessing a demonstration in America.

Mr. T. G. STEVENS showed two interesting specimens: an endothelioma of Bartholin's gland, and an ovarian cyst exhibiting a very early stage of papilliferous growth. The latter gave rise to a brief discussion as to the origin of this type of ovarian neoplasm. Dr. HERBERT SPENCER emphasized the advisability of removing both ovaries in cases of papilliferous cyst where the nature of the growth was discovered at operation.

Mr. J. BRIGHT BANISTER demonstrated a sarcoma of the Fallopian tube; a carcinoma of the Fallopian tube; and a uterus in which the scar of Caesarean section had ruptured at an early stage of labour. On inquiry, he had found the Caesarean section to have been performed at the previous (first) confinement on account of obstructed labour; the uterine wound had been sutured with silk, and the puerperium had been complicated by sepsis. Mr. EARDLEY HOLLAND referred to statistics indicating that Caesarean section scars had ruptured more frequently before the onset or at an early stage of labour rather than later in its course.

Dr. VICTOR LACK communicated a report of a case of cyst development in an autogenous ovarian graft. The graft, subsequently removed, had been found to contain ova in follicles, and follicular cysts. After the primary operation (double oophorectomy and implantation of the graft into the abdominal wall) a period of amenorrhoea had been followed by the re-establishment of menstruation and eventually by excessive uterine haemorrhage. In the few cases previously recorded menorrhagia had similarly accompanied cyst development. This fact suggested an hypothesis as to the relationship of ovulation to menstruation. The PRESIDENT suggested that only the medullary tissue of the ovary should be used for purposes of grafting.

### SPRUE AND COELIAC DISEASE.

At a meeting of the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine on December 3rd a discussion took place on sprue and coeliac disease.

Sir LEONARD ROGERS, in opening, said that a large number of theories with regard to any particular disease indicated that we were ignorant of its real nature; that was especially true with regard to the causation of sprue—a group of symptoms which might be produced by several etiological factors, the essential factor being still unknown. The various theories might be divided into two groups: those suggesting digestive changes, and the infective theories. Of the latter the most important was that which ascribed sprue to the action of the yeast group of fungi. *Monilia pilosis* had also been suggested. It was probable, however, that yeast fungi were merely an aggravating secondary infection. Organisms of the group *Streptococcus viridans* had been identified, and good results had been obtained from the use of oral streptococcal vaccines. The great loss of colour in the stools lent weight to the theory of digestive deficiency, there being an excess of fat in the stools. In order to discover the originating factor of the disease it was necessary to study the early stages. Sir Patrick Manson had stated twenty predisposing causes, from long endemic residence to fistula and miscarriages. Hill-diarrhoea in India was a very important predisposing cause which threw great light on the subject, as the digestive changes in that disease had a suggestive similarity to sprue, and neglected hill-diarrhoea very often developed into sprue. Hill-diarrhoea was not infective, and would immediately cease upon removing the patient to a lower level. There was strong evidence for the belief that deficiency in vitamins was a predisposing cause of sprue, a diet of tomatoes and marmite giving good results, although marmite was an extract of yeast, the very fungus which was supposed to cause sprue. Vaccines had been used with a certain measure of success. Extraordinarily rapid recoveries had resulted from treatment on the theory of calcium deficiency.

Dr. REGINALD MILLER said that owing to insufficient knowledge of the two diseases there was no agreement as

to whether coeliac disease was the same as sprue; but there were notable differences. Coeliac disease always originated in childhood, and, even without treatment, there was amelioration as maturity was reached. It was very seldom fatal, and did not occur in epidemics. Among children the essential feature of the disease was disorder of fat absorption, and it had nothing to do with intestinal disease, in many cases there being no diarrhoea, and usually no ulceration of the tongue. The stools were pale, unformed, frequent, excessively offensive, and contained a large excess of fat. The treatment consisted in withholding fat, and subsequently administering alkalis, the object being to convert irritating fatty acids into non-irritating soaps. Bile salts were also given. He was sure that coeliac disease was not a disease of the pancreas, nor was it an organic disease.

Dr. A. CASTELLANI said that infections by monilia and streptococcus were secondary. He had never had the slightest result from the use of monilia vaccines. He did not agree with the theory that sprue originated in syphilis. He had never found salvarsan treatment successful; alkaline treatment was certainly useful.

Dr. H. H. SCOTT read a paper on the nature and treatment of sprue, which is published in full at page 1155.

Dr. ARTHUR POWELL emphasized the differences between coeliac disease and sprue. In sprue *post-mortem* examination invariably revealed a shrinkage of the liver, great attenuation of the stomach, with loss of epithelium; these conditions were not observed in coeliac disease, which was characterized by enlarged spleen and great pain in the abdomen. Vomiting was more frequent in coeliac disease than in sprue. In coeliac disease the appetite was poor and capricious, whereas, unfortunately, in sprue it was the opposite. There was a tendency to dropsy in coeliac disease, while there was shrinkage of the body in sprue. In sprue he had known the pancreas to show the symptoms of syphilis.

Lieutenant-Colonel W. P. MACARTHUR said he had tried calcium and parathyroid extract with success in cases of sprue.

Dr. Low said he had known cases of sprue—if it were sprue—in which the disease had developed ten years after the patient had returned to England. The curing of the *septic condition* of the mouth had been extremely beneficial, although he believed the effect was secondary. It was extremely difficult to know when a permanent cure had been effected.

Sir LEONARD ROGERS, in reply, said that he thought sprue might be due to the fact that vitamins were not properly digested, and not to any lack in the diet.

### LIVERPOOL MEDICAL INSTITUTION.

At a meeting of the Liverpool Medical Institution held on November 29th, with the President, Professor J. HILL ARNOLD, in the chair, Dr. W. JOHNSON read a note on acute infectious polyneuritis. He said that among the rarer forms of multiple peripheral neuritis was that known as auto-infectious or acute toxic polyneuritis. He gave a short account of two cases he had seen recently and pointed out that the disorder was usually ushered in by what the patient described as a "chill" or "influenza." There might be a variable interval between such a chill and the onset of the neuritic symptoms. These usually began as sensations of numbness and tingling in the toes and fingers, followed by marked motor weakness in all four limbs. Soon, the facial muscles became affected, and this observation, combined with, later, the occurrence of trunk muscle weakness, served to indicate the correct diagnosis. Sensation was dulled over the distal portions of the extremities, but the sensory loss was usually much less marked than the motor loss. Apart from other forms of peripheral neuritis, the condition might simulate Landry's paralysis and acute ascending myelitis at the outset. The peripheral distribution of the symptoms, the disordered sensation, and the presence of facial paralysis were the chief points which would lead to the diagnosis of acute infectious polyneuritis. The cerebro-spinal fluid showed no definite change.

Dr. LEYLAND ROBINSON said that the disease in one of Dr. Johnson's cases might be associated with a transfusion

sufficient accuracy or extent to render it of any value in an ingenious manner by Wassink and Westink-van-Ramsdonk. Starting from Slye's observation of the organ boreality of cancer in mice they interrogated over 1,000 cancer patients as to the cause of death of their relatives without inquiring specifically for cases of cancer. Among the families of 258 cases of cancer of the breast they found 102 cases of cancer, of which 40 were mammary cases. Taking 21—as a basis, and comparing the figures with the general death statistics, they find that the number of cases of mammary cancer in the families of their mammary cancer patients is eight times the figure that would be expected. The authors recognize that patients suffering from cancer in a particular organ would be more likely to remember other cases of disease in the same organ than in other organs in members of their families. In order to correct this error they take Bashford's estimate that one case of cancer may be expected in every two families, and assume that there are no cases of breast cancer among the unreported cases in their series. With this correction the figure is five times what would be expected from the general death figures. Similar evidence of organ heredity was found in cancer of the uterus, skin, lip, and tongue, but was lacking in mouth and throat cancer. This they attribute to the influence of tobacco and alcohol, though it is difficult to see why similar influences should not affect the figures for the lip and tongue. The numbers, however, are much smaller for the last four sites than for the breast, uterus, and skin. A wider application of this method of investigation should give results of considerable value.

#### AN ANTIMOSQUITO CAMPAIGN IN HAMPSHIRE.

At the meeting of the War Section of the Royal Society of Medicine on December 10th Surgeon Commander G. O. M. Dickenson gave an account, based on a report by Surgeon Commander D. H. C. Given, at present abroad, in the Alverstoke district of South Hampshire. The nuisance has been known in the district for many years, and was mentioned in diaries half a century old, but there is evidence that it has become much greater of recent years, and is even likely to produce serious economic disturbance. The district, which comprises Bournemouth Camp and Stokes Bay, is low-lying, and during the spring tides the sea water percolates upwards through the shingle and forms pools which remain for a week or more. The area is also indented by creeks running inland from Portsmouth Harbour. The reasons why the nuisance has lately increased are considered to be that the camp moats are being dammed back by mud brought down by the river Alver; that the river, owing to silting, does not drain the land effectively and has been diverted by the construction of a railway embankment, whereby the original channel was left as a sort of lagoon, which became a prolific breeding ground. When Surgeon Commander Given commenced operations last March he obtained the help of Mr. J. G. Marshall, F.R.S., director of a mosquito control committee on Hayling Island near by, and it was established that the culprit was *Ochlerotatus detritus*, or salt-water mosquito, a species widely distributed around the coasts of Europe, from Denmark to Macedonia, and closely allied to the species infesting the coasts of North America. It breeds by preference in brackish or salt water, and its eggs extensively over the ground from April to October, and passes the winter in the egg or larval stage. The larvae are consumed by shrimps and small fish, and on this account are not found in the moats. The operations against the mosquito were carried out by

a staff of army and navy men. The water level of the moats was reduced by two feet, the outlying pools were sprayed in the spring and early summer with oil and kerosene, and later, to ensure destruction of the eggs, shale oil or fuel oil was applied and lighted so as to form a barrage of fire; over the marshes specially made rakes were used to upturn the light and peaty soil, shallows were pumped out wherever possible and filled with shingle, and the ponds stocked with sticklebacks and shrimps, or with eels, which can live in a stagnant ditch or even in mud for long periods. There had been a marked diminution in the number of mosquitoes during the summer, though there was some doubt whether this was due to the measures taken or to the fact that the season was unfavourable for breeding; Surgeon Commander Given's view was that the season was not unfavourable. In the ensuing discussion Lieut.-Colonel W. P. Macgarrath expressed a doubt whether the species named was the only one concerned. He would have expected other species, notably the *Ochlerotatus caspius*, to be active, and, indeed, in the specimens sent from Portsmouth to Millbank both species were freely represented. Surgeon Commander Dickenson, however, said that the species mentioned by Colonel Macgarrath was found only in very small numbers, and the chief cause of the nuisance was assumed to be the salt-water mosquito, which was present in great abundance. Wing Commander Whittingham and Colonel Crawford Kennedy remarked upon the extraordinary way in which mosquitoes of this species bred at Milota.

#### TIME REQUIRED FOR GALL-STONE FORMATION.

Whilst in laboratory animals gall-stone formation may be induced experimentally in a few days or weeks, sufficient evidence of the time required in the human subject has not been forthcoming. The majority of the cases reported hitherto which are supposed to throw light on the point have been instances in which a surgical examination of the gall bladder was made after an attack of typhoid fever, and the period elapsing between the two has been taken, almost without question, as the age of the gall stones discovered. As calculi may exist during life without giving any noticeable symptoms of their presence it may be objected that their formation was antecedent to the attack of typhoid fever. The presence of typhoid bacilli within the calculi cannot be taken as clear evidence that they were imprisoned by the deposits of cholesterin, for it has been shown experimentally that biliary calculi, rendered sterile, can imbibe organisms from a culture. Cameron would seem to be met. Here the patient was submitted to operation under a diagnosis of cholecystitis. The gall bladder was twice the normal size, acutely inflamed, and tense from distension with fluid. The walls were thin, and no abnormalities of the biliary ducts were found. The first a colourless mucoid material and then normal-looking hepatic duct bile in a free flow. It was concluded that the obstruction to the cystic duct had been due to a mucous plug. The collapsed organ was ascertained by palpation and direct inspection of its interior to be free from calculi or cholesterin deposits, and it was fixed to a catheter for drainage. Normal-looking bile flowed freely for a fortnight, and on the catheter being removed at the conclusion of the drainage, the discharge through the fistulous tract for five days and then ceased. The patient was discharged twenty-four days after operation, but had to return to hospital on the fifty-sixth day on account of pulling pains in the gall-bladder region, accompanied by the discharge of pus from the fistulous tract. An attack of influenza delayed the second operation till eighty-six

SATURDAY, JULY 14TH, 1923.

### RESEARCH AS A PROFESSION.

TOWARDS the end of last February Sir Alfred Yarrow gave £100,000 to the Royal Society to mark his sense of the value of research to the community. He gave it to be used as capital or income, as the Council of the Society might think fit, because he recognized "that conditions alter so materially from time to time that, in order to secure the greatest possible benefit from such a fund, it must be administered with unfettered discretion." To emphasize this point Sir Alfred Yarrow suggested that any rules made for the administration of the fund should be reconsidered by the Council every tenth year, so as to meet modern needs. While leaving the Council this valuable discretion, he expressed his hope that the money would be used to aid scientific workers by adequate payment, and by the supply of apparatus or other facilities, rather than upon erecting costly buildings on which large sums of money are sometimes spent without adequate endowment, so that "the investigators are embarrassed by financial anxieties." He expressed his expectation that care would be taken that "a gift from the fund shall in no case lessen any Government grant."

The Council of the Royal Society has given attention to the best way of using Sir Alfred Yarrow's gift, and has this week published the result of its deliberations. The official announcement states that on reviewing the situation it appeared to the Council "that there was a marked deficiency of positions in which a man who had already proved his capacity could continue to regard research as the main occupation of his life. Consequently at the Council meeting of the 5th inst. it was finally decided to use the larger part of the income in the direct endowment of research by men who have already proved that they possess ability of the highest type for independent research. To this end a number of professorships will be founded, of type similar to the Foulerton Professorships, which were founded by the Society in 1922 for research in medicine. The professors will be expected to devote their whole time to scientific research, except that they may give a limited course of instruction in the subjects of their research to advanced students. There is at present a tendency to regard scientific research as a secondary occupation for men whose primary occupation is the teaching of students. The intention of the Royal Society in founding these professorships is to recognize research as a definite profession."

We make no doubt that the Council of the Royal Society has rightly interpreted Sir Alfred Yarrow's wishes, and it will be observed that the two gifts which have recently been received by it—the Foulerton and Yarrow funds—have enabled it to establish a precedent new in this country at least, and not very common in any other. This new precedent is that research shall be the primary object of the incumbent of one of these professorships, and not, as has usually of necessity been the practice, an occupation secondary to the teaching of students. Sometimes, it is true, the

occupant of a university chair has put research first and teaching second; but as it is his duty to teach, the university authorities may be disposed to grumble—not without some reason. No doubt the stimulus provided by a class of students is useful to some men, but, as Sir George Newman has more than once reminded us, the art of teaching requires special training and, perhaps even more, a special aptitude. A man may be an excellent teacher—many examples will come to mind—and not good at research work. The converse also is true. The two aptitudes do not always exist together, and there have been great scientific investigators who had no aptitude for teaching, except by example to a chosen few who assisted in the laboratory. The result of the great experiment the Royal Society is now able to conduct will not be known perhaps for a generation, but in its hands, and administered, as the donor desires, "by the best people from time to time available," there can be no doubt that the scheme must have a favourable influence on the progress of science in this country.

### VACCINATION PROPAGANDA.

THE Bishop of Gloucester, who a few weeks ago, as we noted at the time, wrote a very incisive letter about the folly or worse of neglecting vaccination, has more recently, in the House of Bishops of the National Assembly of the Church of England, complained of the lack of propaganda in support of vaccination as compared with the activities of its opponents; he seemed to consider that the medical profession in general, and its Gloucester members in particular, had been remiss.

The question raised by Dr. Headlam is worth discussion, and we will admit that the antivaccinationist agitators are past masters in suppressing the truth and suggesting the false, but he is probably not fully aware of what the medical profession has done to make the truth known. Apart from the abundant and incontrovertible evidence of medical authorities writing for their own profession, there has been from time to time a very considerable issue of pamphlets, tracts, and leaflets for the education of the general public. The Jenner Society, of which the late Dr. Bond of Gloucester was the leading spirit, did yeoman service in this way, and also by publishing in the newspapers letters refuting the specious fallacies the antivaccinationists are always ready to put out. The Vaccination League, founded by the late Mrs. Garrett Anderson, did similar work with the help of its secretary, the late Dr. E. J. Edwardes. All these unselfish workers are dead, but in the present day Dr. Arthur Drury of Halifax, secretary of the Association of Public Vaccinators, continues to track out and refute antivaccinationist frivolities and falsities.

The discussion about vaccination, attack and defence, was specially active after the issue of the Report of the Royal Commission on Vaccination, when new legislation was in preparation. The policy then advocated by the British Medical Association and in this JOURNAL was that vaccination and revaccination should be put on the same legislative footing, for both are required for the prevention of small-pox. It was thought that if this could be achieved the exemption of strenuous objectors might be allowed in respect alike of primary vaccination and revaccination, provided that they were willing to go to the trouble of registering their objection with proper legal formalities. The view was that the notoriety of cheap martyrdom had

them—all men of sense will recognize that they speak of what they know.

In the meantime small-pox itself, mild in type though it fortunately be, continues to teach, wherever it appears, the truth about vaccination. The Ministry of Health, in the memorandum it has issued this week (p. 71), states that it regards the situation with concern, and holds the view that there is a distinct risk of an outbreak of a serious character. Small-pox, even when mild, is a hard schoolmaster, but in an individual whoover will take no other instructor has to submit to the risks involved, while those who choose to accept the protection offered them by successful vaccination and revaccination can live with easy minds in the midst of any various epidemic, whether mild or severe.

#### MEDICAL SERIALS IN BRITISH LIBRARIES.

Lack of access to the literature of his subject frequently baulks the scientific worker. The difficulty is perhaps particularly great in London, partly because it has many libraries devoted to medicine and other branches of science. It is a wearisome business to go from one library to another on the chance of finding the particular periodical wanted. In the hope of obviating this waste of time Professor R. T. Leiper, F.R.S., some time ago suggested to the British Medical Association to produce an index or guide to the libraries in which the very numerous scientific periodicals can be found. He has now, with the collaboration of Mrs. H. M. Williams and Miss G. Z. L. Le Bas, M.Sc., prepared such an index. The primary aim of the compilers was that it should be of practical service to researchers, and in the arrangement of the list now issued they have been guided by their own experience and needs rather than by the standards followed by professional librarians. It is hoped, however, that the work they have done will initiate a movement among librarians to bring into effective working some practical scheme to provide London with the many serials it lacks and to eliminate the unnecessary multiplication of copies of little-used periodicals of which there is a surfeit. The time cannot be far distant when financial consideration and restriction of space must impose limitations upon the growth of most London libraries. Frank recognition of this should lead to the early adoption of a plan whereby two copies of every periodical publication can be provided in London; one filed for reference, the other available, under proper conditions, for loan. The list prepared by Dr. Leiper and his colleagues serves to indicate where much of the periodical literature of medicine and the allied sciences may be consulted, not only in London, but also in Cambridge, Oxford, Edinburgh, Glasgow, Liverpool, and Manchester. It is an approximately complete list of such periodicals (including the serials of learned societies available in Britain), and it is believed that few important titles included on account of an ephemeral character have been included on the list. Moreover, many publications have been compiled from library catalogues supplied by librarians or other officials, and from lists made personally by the compilers. Where official catalogues have been published the information contained therein has been many cases and as far as practicable brought up to date. No direct responsibility rests on the librarians or other officials for the correctness of the information, but great pains have been taken to ensure accuracy. It should be noted that the entries for the libraries of the Universities of Edinburgh, Glasgow, and Liverpool comprise only periodicals still current, and are based upon lists recently

a natural attraction for minds of the "anti" type, and that vaccination might rather be hindered than promoted by severe compulsory methods. Parliament, however, unwisely as we believe, declined to make revaccination obligatory to the same degree as vaccination of infants, and subsequent legislation has so shaken the pressure which still remained in favour of infant vaccination that it is now practically optional, though parents even now are reminded of their duty when their babies are about to reach the age of six months. In such circumstances it may properly be asked whether there is any special obligation on members of our profession to adopt methods of propaganda in advocacy of vaccination. In Gloucester twenty-seven local doctors issued in the local press a brief but emphatic statement of their views, which were reproduced in our columns on June 23rd. Are they in addition to spend their time in controversy with any fanatic who chooses to deny that vaccination protects against small-pox? Any man who has a taste for polemics may usefully find exercise for his pen, and it is to be commended if he makes himself acquainted beforehand with the stock sophistries of the letter-writing ring of the antivaccinationists, but it is not all of us who have leisure and inclination. Parliament put aside the advice of the profession, and responsibility for the present position lies at its door. The shower of questions that has been falling in the House of Commons on the head of the Minister of Health is proof that in that House to-day there are many members willing and even anxious to accept it.

The British Medical Association has constantly advocated a sound vaccination policy and lent its support to suitable propaganda. A standing sub-committee, appointed in 1912 to take any necessary action in defence of vaccination, had under consideration the possibility of resuscitating the work of the Jenner Society. The Committee was in advance during the war, and it was ultimately decided that, as the society depended largely for funds and membership upon lay support, the Association could not wholly identify itself with it, though it would continue to lead active support to its work. The Jenner Society is now incorporated with the Research Defence Society. Meanwhile the Imperial Vaccination League had lost both founder and secretary through death, and the Association gladly accepted such assets as it possessed, holding them in reserve for propaganda work. In accordance with a resolution of the Annual Representative Meeting at Cambridge in 1920 the Association made representations on the necessity for more thorough vaccination of the community, and from time to time information on the subject is supplied to members and others seeking advice. The Association's pamphlet, *Facts about Small-pox and Vaccination*, is at present under revision.

The Ministry of Health a year or two ago issued an admirable little tract expounding the value and importance of vaccination. Like Government publications in general, that tract is not popularly known, but it contains much information of the kind the Bishop of Gloucester considers, and very rightly considers, ought to be placed at the disposal of the public. We heard not long ago that the Association of Public Vaccinators have had in preparation a brief exposition of the realities of the case. If they issue such a document, needless to say they will be accused of wholly mercenary motives; but that need not disturb Reports on Public Health and Medical Subjects, No. 8: Small-pox and Vaccination, H.M. Stationery Office, 1931. Price 3d. net.

days after the first. Then a thick-walled contracted gall bladder was found containing numerous calculi of various sizes, the largest measuring 17 by 15 by 12 mm. For the most part they consisted of cholesterolin, with a small amount of calcium and bile pigments. Thus the extreme age of these stones was eighty-six days, although it is highly probable they had already formed within a period of fifty-six days.

#### NURSING IN THE UNITED STATES.

In December, 1918, the Rockefeller Foundation invited persons interested in the development of public health to attend a conference in New York to discuss the status of public health nursing and the education required for training the needed personnel. The result of the conference was that the president of the Foundation appointed a committee of seven in January, 1919, to study the proper training of public health nurses. The committee, amongst whom were such well known authorities as Dr. Welch of Baltimore, Professor Winslow of Yale, and Dr. Stillman of New York, was considerably enlarged, and a year later was asked to broaden the scope of its inquiry to include a study of general nursing education. The report,<sup>1</sup> published this year, is contained in a volume of close on six hundred pages on nursing and nursing education in the United States. The report of the committee, however, covers only thirty of these pages. The remainder of the volume is a survey by the secretary of the committee, Miss Josephine Goldmark, of the exhaustive and detailed investigations, made by herself and several nursing and lay assistants on behalf of the committee, into the conditions of nursing in the United States. These investigators have examined practically the whole field of nursing services, and have left no stone unturned in order to expose the existing conditions and to suggest measures for improving them. Miss Goldmark's survey is divided into two parts—the functions of the nurse and the training of the nurse—and each of these has a number of headings and subheadings, such as public health nursing, the nurse in private duty, the nurse in institutions, the hospital school of nursing, training courses for subsidiary nurses, the university school of nursing, and post-graduate courses. The committee emphasizes the fact that the public health nurse is an all-important factor in preaching the gospel of sanitation in the homes of the people—a fact which has been realized internationally in the present activities of the League of Red Cross Societies. In America 11,000 nurses are employed in this way, but the committee states that 50,000 are required in order to meet generally accepted standards. For hospital and private sick nursing there were at the time of the report 149,128 trained and registered nurses, including the 11,000 employed in public health service, some 11,000 more in hospitals and institutions, and 120,000 in private nursing, the total number representing one nurse for every 700 of population. But in addition to the registered nurses, there were 54,953 student nurses in the hospitals, and 151,996 of an unregistered class of nurses known as "attendants and practical nurses," so that the entire body engaged in nursing work in the United States was equal to one trained or untrained nurse to every 294 of population. The committee recommends the abolition of the untrained nurse and her replacement by a subsidiary class of nurse, to be called a "nursing aide," who should have a definite training, be licensed by the State, and be entrusted with the charge of chronic or convalescent patients, leaving the graduate and registered nurse for public health nursing and for the nursing of serious and acute cases. Three

courses of training for nurses are recommended—one for the subsidiary nurse in smaller hospitals and institutions; a highly organized course for the registered nurse in training schools and hospitals, supplemented by post-graduate courses; and a university course for those undertaking special educational duties. At the close of the training in a university school of nursing the student would receive a diploma and a bachelor's degree in nursing or in science. The committee considers that these university schools of nursing are of fundamental importance in the furtherance of nursing education. The volume contains material which should be studied by all engaged in nursing services, and especially by hospital and public health administrators. If the committee's proposals are ever carried out in their entirety the nursing profession in the United States will reach a standard so far unequalled in any other country. The one thing lacking, however, in this highly organized education is the element of human sympathy, which is an essential attribute of the nurse, but cannot be taught. There is also the danger of overnursing in a community where the proportion of nurses is very high.

#### COCAINE AND COCAINE SUBSTITUTES.

THE report published in this issue (p. 1154) of the discussion at the Royal Society of Medicine on the comparative value of cocaine substitutes is interesting as summarizing the present attitude of different branches of the profession to cocaine and its substitutes. The quiescent satisfaction with which medical practitioners had for some years regarded cocaine and its substitutes—using cocaine chiefly as a surface anaesthetic and novocain and stovaine as infiltration anaesthetics—was disturbed by the notoriety which the vice of cocaine-taking had gained in this country, giving rise to stringent regulations by the Home Office governing the sale of cocaine. In May last a committee was set up by Mr. Neville Chamberlain, then Minister of Health, to inquire into the whole question of cocaine and cocaine substitutes. This committee issued a circular to members of the profession thought most likely to be specially interested, but has not yet been able to make its report. Among the reasons for setting up the committee were the encouraging reports of a new cocaine substitute named butyn, a synthetic product discovered in Chicago in 1918, by the Abbott laboratories working in collaboration with Professors Roger Adams and Oliver Kamm of the University of Illinois. A committee of the Section of Ophthalmology of the American Medical Association reported in 1922 that butyn was more powerful than cocaine, acted more quickly and for a longer time, was less toxic, had no effect on the size of the pupil, had no ischaemic action and therefore caused no shrinking, could be boiled without impairing its efficiency, did not deteriorate by keeping, and had no attraction for the drug-taker. Mr. W. M. Beaumont<sup>1</sup> reported favourably on it, more particularly from the ophthalmological point of view, and said that he believed butyn to be superior to cocaine as a local anaesthetic. At the Annual Meeting of the British Medical Association last July Dr. William Hill<sup>2</sup> expressed the opinion that butyn might be a useful alternative where cocaine was contraindicated, and emphasized its low reported toxicity as compared with cocaine; on the other hand he pointed out that the cost of butyn was five times that of cocaine, that it was not uniformly reliable, having quite failed to anaesthetize on certain occasions, and that it did not produce shrinking. More recently Mr. Eric Watson-Williams<sup>3</sup> published a preliminary note of some experiments on the toxicity of cocaine, butyn, and other cocaine substitutes, which had

simply the absorption of a negligible amount of morphine. The evil effects of excess of opium smoking are too obvious to be easily explained away.

I cannot close this letter without drawing attention to a remarkable little book by Dr. Giles, the professor of Chinese in Cambridge, entitled *Some Truths about Opium* (1923). He gives the history and some of the effects of opium in China. His views are those rather of the Royal Commission than others who periodically raise a scare in Europe. He says:

"An opium-smoker may be a man of exemplary habits, never even fuddled, still less stupefied. He may take his pipe because he likes it, or because it agrees with him; but it does not follow that he must necessarily make himself, even for the time being, incapable of doing business. Wine and moonlight were formerly considered indispensable by Chinese bards; without them, no inspiration, no poetic fire. The modern poetaster who pens a chaste ode to his mistress's eyebrow, seeks in the opium pipe that flow of burning thoughts which his foreheaders drained from the wine-cup. We cannot see that he does wrong. We believe him to be a moderate user of the drug is attended with no dangerous results; and that moderation in all kinds of eating, drinking, and smoking is just as common a virtue in China as in England or anywhere else."

My object in quoting this from the pen of a man who spent many years of free intercourse with the people as well as the officials of China is to show that even some voices may have a good side if practised with moderation. Intemperance language may be a means to an end in politics, but it has no part in science or medicine, and to overstate the case as to drug addictions can in the end serve no useful purpose.—I am, etc.,

## COCAINE HABIT FROM EYE DROPS (?).

Sir,—The following case raises a question of some general interest:

A woman aged 56 recently consulted me for rapid deterioration of visual acuity in the right eye. Examination of the fundus revealed the thrombosis of the superior temporal retinal vein. The right pupil was moderately dilated and fixed. A mucocoele of the right lacrymal sac was present. Questioning of the patient revealed that in 1901 a well known surgeon had been consulted for a swelling over the area of the right lacrymal sac and for the condition had ordered 5 per cent. cocaine drops, to be followed in a few minutes by zinc sulphate drops. The patient never returned for further consultation as advised, but had persisted in the use of these drops twice daily ever since (twenty-two years). Considerable difficulty has been experienced by me in endeavouring to persuade the patient to give up the cocaine application and substitute a milder, although the increased likelihood of glaucoma becoming added to the already diseased eye was explained.

The unwillingness to give up the cocaine would appear to suggest that a cocaine habit of a mild nature had been formed. Therefore it seemed to me that this case was worth recording.—I am, etc.,

F. C. PRUMER, M.D.,  
Honorary Assistant Surgeon,  
St. Paul's Eye Hospital, Liverpool.

November 29th.

## THE ETIOLOGY OF MEASLES AND OF SCARLET FEVER.

Sir,—In the *British Medical Journal* (October 27th and November 10th) short accounts are given of the recent research work on the bacteriology of scarlet fever. The valuable results obtained by G. Caronia and M. B. Sindoni<sup>1</sup> are therein mentioned, together with the results reported by his latest papers<sup>2</sup> must be well distinguished from those obtained by others who have not supported their morphologic and cultural findings by sufficient proof, neither by serologic and immunologic tests, nor by experimental transmission of the disease to animals or—what is more important—to human beings. Professor Caronia has full right to claim that the micro-organisms, first described by Dr. Cristina in December, 1921, and afterwards accurately studied by him—foster<sup>3</sup> and that the other micro-organisms which he has been

The micro-organisms which is constantly visible in smears from the bone marrow, from the spleen, from the scales, from the centrifugized urine,<sup>4</sup> and from the filtrate mucus of scarlet fever patients, is a very small coccus which is often united in pairs (otherwise the cocci are isolated) and can be grown in an indefinite series on anaerobic culture media (Dr. Cristina or Tarozzi-Mogroni type). The same organism constantly grows on these culture media when blood, cerebro-spinal fluid, filtered urine,<sup>5</sup> filtered extract of scales,<sup>6</sup> and filtered nasopharyngeal mucus<sup>7</sup> is inoculated into them. Sufficient evidence has been brought to demonstrate that the micro-organisms passes through an ultra-microscopic phase (the microscopically visible forms can be obtained by culturing the filtrate of well developed cultures).

From measles patients a similar organism can be isolated and cultivated (in the same way as before said). This micro-organism, which Professor Caronia was the first to isolate, to describe, and to prove to be the specific agent of measles, is morphologically different from the scarlet fever agent: it is Gram-negative and the cocci have a nearly round form, whereas the scarlet fever cocci are slightly oval in form and are Gram-positive.

All the serologic and immunologic tests prove the scarlet fever cocci to be different from the measles cocci. The specificity of these germs (the scarlet fever as well as the measles germs) is proved with certainty by the following facts:

1. An antigen prepared from the cultures reacts positively to the antibodies contained in the blood serum of scarlet fever (or measles) patients (agglutination, complement fixation, opsonic index).
2. Young rabbits inoculated with these cultures develop a disease which is in many features similar to human scarlet fever (or measles); redness of the skin can be detected, which is followed by evident desquamation. The blood serum of these infected animals (rabbits) reacts positively to an antigen prepared from the scales of scarlet fever patients.
3. The inoculation of carefully and duly dosed cultures, to children in an aseptic state, is followed by an attenuated form of scarlet fever—

in an aseptic state, is followed by an attenuated form of scarlet fever—childer acquire a definite immunity. These experiments, which have always been governed by the main thought of doing no harm, and were done in children only after they had been proved to be quite harmless (the authors previously inoculated cultures of the scarlet fever agent to themselves, developing a very attenuated form of scarlet fever), were never followed by any ill consequences.

4. The inoculation of dead cultures to healthy children has an immunizing effect; these children, though kept in close contact with immunized patients, do not develop the disease; their tonsils can be harmlessly swabbed with the nasopharyngeal discharge of sick children in the rash period.

This success in vaccinating children by means of dead cultures, besides being an important proof of the specificity of the diseases, and of Caronia's germ, is a result of the utmost importance. In diseases so serious and frequent as scarlet fever and measles it is essential that the value of a preventive vaccine of so great an efficiency should be generally acknowledged. Doubt is no longer possible as to the vaccinating efficiency of killed scarlet fever and measles cultures. In our clinic scarlet fever and measles patients are kept in the same room and in neighbouring beds; in six months some hundreds of children have been thus kept in our clinic after having been vaccinated against the disease—no scarlet fever child belongs have always been vaccinated against the disease. All members of the families to which a scarlet fever child belongs have always been vaccinated against the disease, and the vaccine has never failed to protect the grown-up people as well as the children against the infection. Evidence of the prophylactic efficiency of the vaccine has already been brought from many parts of Italy where scarlet fever epidemics have in these last months been noted; many families of sick children and all scholars of some infected schools have been there vaccinated. The experiments of evidence of various authors, and are to be repeated by the French and German investigators.—I am, etc.,

brought him to the conclusion that butyn was at least as dangerous as cocaine. In three of the fatal cases reported by Mr. E. Watson-Williams cocaine was, however, applied as well as butyn, and one death was clearly due to an overdose of butyn. At the joint discussion at the Royal Society of Medicine the consensus of opinion seemed to be that as no other drug than cocaine combines ischaemic and anaesthetic properties no existing substitute can effectively supplant it; that the claims made for butyn as regards freedom from toxicity are apparently unfounded; and that with the control now exercised in this country the possibility of abuse by narcomaniacs need not concern the surgeon. At the same time it may perhaps be suggested that cocaine is often used in unnecessarily large quantities. In 1888 De Havilland Hall showed that the alkalinization of cocaine solution by a trace of sodium bicarbonate greatly increased its anaesthetizing powers. A. Abraham<sup>4</sup> recently stated that he had found a 3 per cent. solution of cocaine to be as effective as a 20 per cent. solution in inducing surface anaesthesia, provided that potassium sulphate (2 per cent.) was added to the solution up to a quarter of its amount; this confirms the observation of Hirsch in 1920.

#### POIKILOCYTES IN NORMAL BLOOD.

DRESBACH in 1904 described a case, a normal healthy young adult, in which 90 per cent. of the red blood corpuscles were elliptical in shape, the average length of the corpuscles being two and a half times that of the average breadth. In all other respects the appearances were normal. Ten years later Bishop found a similar condition in the blood of a young male who was suffering from appendicitis, 75 to 80 per cent. of the red corpuscles being elliptical. The possible effect of mechanical distortion in making the preparations could be eliminated. The sister of this patient showed the same abnormality, an observation which suggested some congenital peculiarity. Huck and Bigalow<sup>5</sup> now add another case. Fresh preparations made from the blood of a strong healthy female medical student disclosed elliptical and elongated red cells forming between 53 and 84 per cent. of the total erythrocytes. No nucleated erythrocytes could be found, and the various leucocytes and platelets were normal, as was also the haemoglobin estimation. Wet preparations preserved for a period of three weeks showed no increase in the percentage of abnormal forms, in marked contradistinction to the phenomena observed in the so-called "sickle-cell anaemia," of which an account was given recently (p. 1109). The mother of this patient had the same blood peculiarity, but none of the rest of the family. The patient herself has several times acted as a blood donor, and no untoward effects have been noticed in the recipients; indeed, in one patient with secondary anaemia who recovered no elliptical cells could be found after two months. We may conclude, therefore, that the anomaly is inherent in the cells, and cannot be transmitted by intravenous injections of blood. Hereditary transmission, while not definitely established, is probable.

#### PELLAGRA AND MAIZE.

As we had recently to recall, the etiology of pellagra is still in doubt. There is some evidence that it belongs to the class of deficiency diseases, and the oldest theory is that it is associated in some particular way with a diet of maize. This theory has been called into question over and over again, and fresh evidence against it is afforded by a recent bulletin issued by the American Relief Administration. When it was decided early in 1922 to send seven

million bushels of maize to Russia the wisdom of choosing that cereal was questioned on the ground that its use as an exclusive diet might be expected to lead to an outbreak of pellagra in the famine area such as had occurred in Rumania in 1916. The ordinary diet of the Rumanian peasant consisted of corn meal mush, milk, and onions; pellagra made its appearance soon after the milk element of this diet disappeared, when the German invaders drove off all the cattle. Mainly because the money available for relief in Russia would buy two and a half times as much maize as any other cereal, it was decided to risk the chance of pellagra, for, as one of the administrators expressed it, "corn (maize) was the sole hope against death; Russia had got beyond the fear of disease." In the result no outbreak of pellagra occurred; in the whole of the Volga famine district not a single case was reported. In Ukraine there were twenty suspected cases which were specially investigated. Of these only four were found to be suffering from true pellagra, and not one of the four had eaten any of the American corn. The supplementary food of the Russian peasants was negligible, for previous to the arrival of the corn they had existed on the bark of trees, clay, weeds, and even human flesh. With maize as their sole article of diet, nevertheless, they did not develop pellagra.

#### SMALL-POX AND CHICKEN-POX IN THE UNITED STATES.

A RECENT report<sup>1</sup> by Dr. Hugh S. Cumming, Surgeon-General of the United States Public Health Service, contains some interesting data as to the prevalence and fatality of notifiable diseases in 1922. In health administration the several States are independent of each other, and to a large extent of the federal authority, so that returns are not always strictly comparable, case rates and death rates having a significance depending partly on differing standards of local vigilance and of reporting by practising physicians. Even the total populations dealt with are not absolutely identical, though very nearly so. In forty-three States and three Districts (population 103,318,256) the small-pox cases reported in 1922 numbered 1,691, as contrasted with a "median" of 60,914 in 1913-21. The fatality rates differed immensely as between State and State. In Arizona there were 134 deaths in 468 cases, or 28.6 per cent., and in Colorado 270 deaths in 1,026 cases, or 24.9 per cent. Next came Missouri with 82 deaths in 657 cases, or 12.5 per cent., Kansas with 68 deaths in 842 cases, or 8.1 per cent., and Oklahoma with 57 deaths in 736 cases, or 7.7 per cent. These States adjoin each other in the north-west central and south-west central parts of the United States. Pennsylvania and Maryland, in the north-east, had each a 5.9 per cent. fatality rate, but the total cases were only 102 and the deaths 6, so the figures are not important. At the other extreme from the high fatality of Arizona and Colorado, a number of States were well under 1 per cent. in their case mortality. Of the total 31,691 cases in the year 1921 proved fatal, so that the fatality rate over all was 2.63 per cent. Making every allowance for imperfect returns it would seem fairly certain that very different types of small-pox have gone to make up this average rate. Dr. Cumming's report, being only statistical, does not comment on questions of prevalence or types or fatality, and small-pox is only one of twenty-four communicable diseases dealt with. The statistics of chicken-pox are of interest in the present connexion. In forty-six States and three Districts (population 107,325,283)

<sup>1</sup> Public Health Reports, Vol. 33, No. 44. Washington, 1923.

<sup>2</sup> The word "median" is not quite identical with "mean" or "average," but is used in preference, and "has been defined as the middle item in an array. If the numbers of cases in the array are arranged so that the greatest number reported in any one year is first, the second greatest number is second, and so on, then the number of cases in the centre of the array is the median."

PIGMENT AND CANCER.

Sir,—May I be allowed to endorse the opinion of Sir George Beatson (December 1st, p. 1566) as to the importance and value of the Bradshaw Lecture on melanosis by Mr. W. G. Spencer? It is very probable that a definite knowledge of the mode of origin of pigment would be most helpful in ascertaining the nature of melanotic cancer.

Spencer considers, as did Beatson in his paper on the possibility of a pigmentary origin of cancer (*Lancet*, 1922, ii, p. 655), that melanin pigment is not derived from haemoglobin; though it is interesting to note that the latter, in his letter, regards nutrition as a primary factor in its production, and refers, moreover, to the admitted connection between chlorophyll and haemoglobin. I have recently endeavoured (*Journal of the R.M.C.*, October, 1933) to revise the view formerly in favour that pigment is derived from haemoglobin—as a product of haemoglobin on the part of epidermal cells. It is known that various chromogen groups are contained in or can be obtained from haemoglobin.

In melanotic cancer I would consider the pigment production a concomitant result of increased and modified haemetallic activity on the part of the cancerous cells rather than as the exciting cause of the growth. One or two observations brought forward by Spencer appear to me to militate against Beatson's view; namely, (a) that horses which keep their hair dark—that is, strongly pigmented—rarely suffer from melanotic cancer; and (b) that human races (to which may be added the fact of their pigmented skin), yet melanotic cancer is apparently very rare among such. If pigmentation were concerned in the causation of these growths, should we not expect to find them occurring particularly in these two groups?

Spencer points out that cancer tends to arise in the areas of pitch-black pigmented skin, but only in grey horses which are turning white with increasing age—that is, in which pigment production generally is falling. I would suggest that the development of the malignant behaviour in such cases may indicate a biological reaction on the part of the cells concerned to an excessive degree of pigment production, correlated with the general failure of the cells to produce pigment—normally as well as abnormally. In the case of one or both of these types of cells this particular function becomes changed, at any rate largely, into one ministering directly to their growth, nuclear increase, and resultant proliferation. In other words, I agree with Dr. Charles Creighton that such cells have become cancerous because they have taken to living on the blood elements.

On the other hand, again, in white peoples, the normal haemetallic function of pigment formation is very largely in disuse (customarily, as regards the general epidermis). Pigmented areas indicate, I would say, an (abnormal) exceptional retention of this property; already there is a special form of haemetallic in unusual degree. Such cells, therefore, may in the circumstances be particularly liable to go a step further and develop malignant behaviour.—I am, etc.,

London, S.W., Dec. 4th.  
H. M. WOODCOCK.

CANCER AMONG NEGROES.

Sir,—From time to time I notice in the *Journal* references to cancer among negro races. Some seem to assume that it does not exist. I had imbibed that theory, and hesitated to remove a tumour that had all the appearance of an early scirrhus of the breast. I was away from the station (Bandawe, Nyasaland) for some time, and when I next saw the patient the tumour was insuperable. It ran an uninterrupted course, completely destroyed the breast, then the soft structures of the chest wall, and then ate through the ribs; when I last saw the negro in her village I could see the heart pulsating. That was just before her death. I have since made it a rule to excise all mammary

tumours whenever the patient will agree. I have also seen epithelioma of the face. In this case the eyelids and the whole of one eye were completely destroyed, and the bone of the eye socket was attacked; the case was insuperable. I have seen a tumour, fungating and evidently malignant, that had practically split the bones of the face, causing the eyes to bulge laterally and giving a strange chameleon look to the patient. It was insuperable. I believe I have seen cases of malignant disease of the liver, but as there was no autopsy the diagnosis was not confirmed. I have removed many large tumours of the testicle which, if not cancerous, are of a nature unknown to me. Keloids and fatty tumours are very common.

Cancer of the lip or mouth I have never seen. Natives cook their food in earthen pots without handles, and as these pots have to be lifted between the two hands I doubt whether the food is ever so hot as we Europeans cook it. It is always allowed to cool a little before it is divided out for eating. The throat cancer attributed to hot rice among the Chinese is not seen here. They are insuperable smokers, but they do not smoke as Europeans do. They do not go about with an irritating pipe stem between the teeth or a cigarette between their lips. The fashionable pipe supplies a cool smoke. The lips are everted and applied to the end of the pipe like a rubber suction play-thing one sees children with at home. One wonders where the smoke is going. Then there is a deep grunt of satisfaction. The pipe is removed, the end wiped carefully, and passed on to the next. But you watch number one, who sits till there is a dazed look in his (or her) eyes and then smoke emerges slowly from the nose like pearls from a lum. Where this has been accommodated is a source of wonder. But the native has got full value from a very economical portion of tobacco and there has been no prolonged irritation of the lip.

If there is a relative immunity to cancer I do not think we can attribute it to the absence of a meat diet. The negroes, when they can get it, eat far more meat than the white people. There is no limit to the variety of the condition, and some might wonder whether there is a limit to the quantity. They are only vegetarians when there is nothing else to be had. Anything from a gelatinous to an elephant is welcomed. The meat may still be warm when magots have to be beaten out of it. Even the skin of a hippopotamus is stored away and cooked when other meat is scarce. It makes a dish something like a jelly. My native carpenter calls it "give." I do not think we can attribute even relative immunity to the lack of a meat diet. There is one element in modern life of which the white races have more than their share, but which is an almost complete stranger to our coloured friends. That is worry. Most of us have seen malignant disease follow periods of great grief or prolonged worry. The negro does not worry. His grief may be acute, but it is brief, and there is no attempt at repressing the emotions. A mourning for the dead means a flood of tears while it lasts. In that there is relief. May not suppressed emotions and the prolonged worry associated with so many callings in life at home be determining factors?

As present we have no reliable vital statistics. The causes of death among the bulk of the population of our African dependencies are still to be investigated. An outbreak of sleeping sickness arrests attention, as does an epidemic of small-pox. But the bulk of the people die and are buried without any medical man making any inquiry whatever. There is immense scope here for medical men who have the time and the talent to devote themselves to the study of disease. A medical missionary may find a maternity case and a cataract case only incidents in an already overcrowded day. We find microscopic work on the blood, stools, and urine too capitalistic to allow of our studying the gross pathological conditions. But there is immense scope for the pathologist, and a very interesting field for investigation would be the tumours affecting natives. I am, etc.,

Kasungu, Nyasaland, Sept. 17th.  
GEORGE PRENTICE.

there were 131,018 notifications, and in forty States and three Districts (population 98,252,556) there were only 70 deaths, the fatality rate being 0.05 per cent., or one death in 2,000 cases. The largest prevalence was in Pennsylvania, but among 19,112 cases not a single death was recorded. In Illinois there were 13,442 cases with 13 deaths, or 0.1 per cent., and in New York there were 15,481 cases with 16 deaths, again 0.1 per cent. Taking the total figures set down for small-pox as contrasted with those for chicken-pox, the small-pox fatality rate, low though it was, was fully fifty times as high as the chicken-pox fatality rate. Where the small-pox fatality rates were very low the figures for the two diseases more or less overlapped, but the broad indication would seem to be that, notwithstanding possible errors in individual cases, the profession in the States has been fairly able to recognize the distinction between chicken-pox and the mild type of small-pox, just as the two diseases have been distinguishable in this country. To this subject of the comparative diagnosis of these diseases two contributions were published in our last issue, the one by Dr. Painton, illustrated by a set of photographs on special plate paper, and the other by Dr. G. F. Rigden. Both writers have had experience of recent events in Gloucester and Gloucestershire. As regards prevalence apart from mortality, the seven American States in which there was most small-pox, measured by the number of notifications per 1,000 of population, were Oregon 1.41, South Dakota 1.32, Arizona 1.27, Washington 1.13, Montana 1.07, Colorado 1.01, and Wyoming 1.00. The seven States with most chicken-pox, similarly measured, were Vermont 4.17, Columbia (District, not State) 2.71, Mississippi 2.34, Pennsylvania 2.13, Virginia 2.03, Illinois 2.01, and Wisconsin 2.01. It will be observed that no State appears in both of these lists.

A POST-GRADUATE course on diseases of the nervous system will be held at the National Hospital for the Paralysed and Epileptic, London, from February 4th to March 28th, 1924. It will consist of clinical lectures and demonstrations, attendance in the out-patient department, and pathological lectures and demonstrations. The fee for this course will be five guineas. If there are sufficient applicants there will be a special course of lectures on the anatomy and physiology of the nervous system (fee, two guineas). A series of clinical demonstrations on methods of the examination of the nervous system (fee, two guineas) will be given. A course of eight lectures and six demonstrations on neurological ophthalmology has also been arranged; the number for this course is limited, so that applications should be made early. The fee will be five guineas as a separate course, or three guineas if taken as part of the general course. A limited number of students can be enrolled as ward clerks or as clinical assistants in the out-patient department. Applications should be addressed to the secretary of the medical school at the hospital (Queen Square, W.C.1).

DR. JAMES GRANT ANDREW, who two years ago retired to Bournemouth, died very suddenly there on December 6th. After making a recitation at a Scottish graduates' dinner he fell back in his chair and immediately expired. He was consulting surgeon to the Victoria Infirmary, Glasgow, and had served on the Council and many committees of the British Medical Association.

OWING to the Christmas holidays all communications and advertisements intended for insertion in our issue dated December 29th should be received not later than Saturday morning, December 22nd.

## ANNUAL DINNER OF THE ROYAL SOCIETY OF MEDICINE.

THE annual dinner of the Royal Society of Medicine was held at the Hotel Victoria on Tuesday evening, December 11th. Sir WILLIAM HALE-WHITE, K.B.E., President of the Society, was in the chair, and the principal guest was H.R.H. the Prince of Wales, who recently became an Honorary Fellow. The other guests were the Archbishop of Canterbury, Viscount Haldane, and Sir W. Joynson-Hicks, M.P. (Minister of Health). About 500 Fellows attended, and among those supporting the president at the principal table were: Sir Humphry Rolleston, Sir John Bland-Sutton, Sir Anthony Bowlby, Sir William Macpherson, Sir Robert Hill, Sir W. Arbuthnot Lane, Sir Berkeley Moynihan, Sir Thomas Horder, Sir StClair Thomson, Sir William Willcox, and the presidents of the Sections.

### *The Progress of the Society.*

THE PRINCE OF WALES, who was enthusiastically received, proposed the toast of "The Royal Society of Medicine." He said that he had been looking through the history of the parent body, the old Medical and Chirurgical Society, and he noted the advice given by one of its former presidents, Sir Benjamin Brodie, who urged all, and especially the young, to abstain from medical politics and to keep away from exciting and irritating discussions. He thought that advice very sound, and his object that evening was not to start any irritating discussions, but chiefly to say how deeply he appreciated the honour which the Society had conferred upon him by electing him to the honorary fellowship. Someone had said that society would be happier if there were no societies, but the Prince thought that the community was well able to look after itself in this respect. The law of the survival of the fittest was merciless where learned bodies were concerned. If any learned body failed to prove its worth no artificial feeding would prevent it from becoming a learned corpse. But when a society, having started from small beginnings, developed into an institution of increasing numbers and prestige so that its name was known and honoured throughout the world, one could be quite sure that the world had real need of it, that it had a genuine job to do, and was doing it very well. He did not think anyone could dispute that the Royal Society of Medicine belonged to this latter category, though it was not for him as the youngest honorary fellow to praise its work or predict its future. The Society was a federation of sixteen distinct medical bodies, each of which existed at one time separately in the interests of its own particular branch of medical science. Twenty years ago, with a wisdom that did them credit, they decided to fuse their separate existences into one body representing medical science as a whole. The Royal Society of Medicine was the result of the fusion, and as a consequence all its elements had grown not sixteen but sixtyfold stronger. This achievement was largely due to the energy and perseverance of Sir John MacAlister, who might well be proud of his achievement, as the Society was proud of him. (Applause.)

Sir W. HALE-WHITE, after thanking the Prince, said that the Society was manifestly prospering. It numbered four thousand Fellows and Members. During the past year it held one hundred meetings. To its library—the largest and best equipped medical library in the Empire—2,000 books had been added, making 120,000 in all. During the year it had sent out 3,000 parcels of books to Fellows resident in the country or overseas, in addition to the books lent to those in town. The number of Fellows who wrote for information which was to be gathered out of the library was so great and their wants so particularized as to consume the whole time of one official. The library contained 4,000 medical prints, which, thanks to the kindness of Dr. Arnold Chaplin, would presently be catalogued, remounted, and indexed. He paid a tribute to Sir John MacAlister, the best of friends and the wisest of counsellors, and to the indefatigable staff, honorary and other, all of whom pulled their weight. The year 1923 had seen the Society breaking new ground in two directions. The Society, as His Royal Highness had said, was the result of an amalgamation of some sixteen others. Owing to the development and advance of medicine, several special Sections had had to be added, so that the Sections now numbered twenty-four. It was

THE USE AND ABUSE OF OBSTETRIC FORCEPS.

Sir,—I hope that this comment on the discussion as to the use and abuse of obstetric forceps will reach you before the subject has become stale or the correspondence on it been closed owing to the "violent passions aroused." It seems to be one of those medical questions which touch us all too nearly to allow of its being discussed with the necessary scientific detachment. My own experience in the obstetric art is gained from abnormal cases among Asiatic slum dwellers—Chinese, Malays, and Tamils. As the national customs of these races strictly forbid the presence of a male midwife in the lying-in room of their women folk, it will readily be understood that I only attend those confinements which show some definite abnormality. By far the most common symptoms for which I am called in is delay in the second stage, due to the simple atonic inertia to which these anaemic malaria-ridden mothers are subject. In former days it was my practice to apply forceps in nearly all these cases, using every care to avoid damage and carefully repairing what I did do. I get very much better results now from an injection of pituitin, surely the busy obstetrician's best friend. A point which surprised me in the discussion was the opinions expressed as to what constitutes serious delay in the second stage. My first question to the importunate messenger sent to call me is, "How long is it since labour pains came on?" It is only rarely that the period stated is less than twenty-four hours, and three days is quite a common answer. The oedematous condition of the genitalia and the general condition of the patient usually bear out the statement. Yet, if the mother is not up and about her usual avocations two days later the husband is apt to regard both the practitioner and the mother as dismal failures.

The squatting position is used by most Asiatics, and in reply to Dr. Farbar's question as to its efficacy I would say that it largely depends on the state of the abdominal musculature. Given a multipara with a haecid abdominal wall there is a tendency for the heavy uterus to fall forward early in labour and the expulsive powers then tend to spend themselves in a wrong direction. I well remember the case of an elderly Tamil to whom I was called after she had undergone two days of the ministrations of a local handwife. The labia were greatly swollen and oedematous and bleeding from tears made by predecessors—for your native accoucheur regards the vulva as the only obstacle in such cases—and the uterus projecting forward over the pubis. On putting the patient in the dorsal position and making a little gentle pressure on the fundus the child was delivered at once and without difficulty.—I am, etc.,  
G. WAGAN SCOTT.  
Sungei Siput, N.  
Perak, Federated Malay States, Nov. 5th.

**DIFFICULT MIDWIFERY IN GENERAL PRACTICE.**  
Sir,—For some reason or another the general practitioner is extraordinarily sensitive to anything which he can construe as criticism of his midwifery. A respectful attitude was obvious at the Portsmouth meeting, in regard to which your leading article of October 6th reminded me that "a gentlemanly note did appear to find its way into the discussion." The correspondence on Dr. Laker's address illustrates this seemingly inevitable effect of papers by obstetric specialists upon general practitioners. It is the natural tendency of every animal (including specialists and G.P.'s) to defend itself when attacked, and we have a letter from a practitioner giving the tongue lashing of "Don don't know your job" in the shape of the proposal that "practical midwifery should be taught by a general practitioner and not by a specialist," and one from a consultant explaining the point of view of those engaged in hospital practice and teaching. I would supplement what Dr.

Victorian conceptions of the relationships of anatomy to medical science. His remarks on anatomical nomenclature call, however, for some comment.

It may be readily admitted that the present position of anatomical nomenclature is chaotic and reflects little credit on the profession or on professional anatomists. Prior to the introduction of the Basle nomenclature in 1895 there were about 30,000 names, duplicates, and synonyms employed in human anatomy. The Basle commission, by insisting on the principle of one structure one name, reduced these to about 4,500, and at the same time suggested that related terms should, as far as possible, be similar; thus, femur, femoral artery, femoral vein, femoral nerve. It is neither logical nor scientific to retain "femoral" for the vessels and "anterior crural" for the nerve. Similarly the main nerve trunks of the superior extremity—an adjective open to objection—were renamed from their positions—radial, medial, and ulnar; and hence, to the consternation of the older generation, the term "musculo-spiral"—that is, a chaotic freedom to call one's own tongue. Your reviewer imagines that a small band of die-hards are going to impose what they are pleased to call an "old terminology"—that is, a chaotic freedom to call any structure in the human body anything one pleases—the scientific members of the profession all the world over. He is offended by seeing "hilus," the abbreviated form of hilum, consistently spelt "hilus," which he apparently attributes to ignorance. He does not appear to be aware that it is really the other way about—"hilum" was derived from "hilum"; and in any case, the Basle commission, which included, I believe, Sir William Turner, Professors D. J. Cunningham, G. D. Thane, and some 120 other non-German European members, dropped "hilum" entirely, and substituted "hilus" in accordance with another of their general principles—that every term should be philosophically correct, and as short and simple as possible.

Very unfortunately, as I think, the Basle commission sanctioned two series of descriptive terms, the one only applicable to the human body, the other equally applicable to all animal forms. Your reviewer prefers the former; I to the latter. On this point I hold the strongest views. To say that "the transverse colon is in contact cranially with the liver and gall bladder" is "un-English," is ridiculous. Presumably your reviewer would have preferred some such term as "above" or "superiorly," ignoring the fact that such expressions are not here equally applicable to the embryo or the quadruped. Is it to be imagined that it is to-day possible, or even desirable, to teach human anatomy to medical students without constant reference to embryology, comparative anatomy, and even pathology—that is, normal anatomical relations as disturbed by disease? What other term but "cranial" is equally applicable, equally scientific, and equally intelligible? A precise science should have a precise language, and such expressions as "above," "beneath," and "behind" leave the reader constantly guessing as to what the author really does mean. Surely the time has come, if indeed it is not long overdue, for English-speaking anatomists to determine finally their own nomenclature. Aided by the physiologists and the clinicians, who have to use our terminology, we might even yet arrive at a mutually satisfactory nomenclature which shall be of general applicability, and at the same time, be precise, concise, English, and scientific. To deny the B.N.A., because it is not altogether correct, is described as of foreign origin does more credit to the

quite natural that each Section should think itself very important, and so it came about that there was a tendency—only a slight tendency—for some Sections to forget that they were but members of the whole body. There was no such thing as a clear-cut specialty, and it was very necessary if the Society was to function properly that the Sections should realize that they were members one of another. Therefore, during the summer, the presidents of all the twenty-four Sections met together and decided that, in order to prevent any possibility of narrowness, meetings of several Sections together, or even of the whole Society, should be held to discuss subjects of common interest. These discussions were now taking place from time to time, and he anticipated that they would add not only to the usefulness but to the renown of the Society. The other function in which the Society had broken new ground was in the formation of a Section of Comparative Medicine. It was an extraordinary thing that in the history of medicine the diseases of animals and the diseases of man should have been treated separately. Until recent times the diseases of animals had not been studied at all, in spite of the fact that several great men in medicine—Jenner, for example—had shown that diseases in animals and in man were in many respects similar, though, on the other hand, they frequently differed. In natural science knowledge was acquired by observing how phenomena resembled one another and how they differed from one another. Clearly, therefore, it could only be to the general advantage to study disease as it existed both in animals and in man, and even to extend the study into the plant kingdom. After all, animal and vegetable life had many common characteristics: they were subject to much the same chemical changes, and disease in both cases was nothing but a perversion of the normal processes of life. One instance of the importance of animal diseases in relation to man was that common disease known as simple goitre. This existed not only in man but in many animals. It was known to be due to a deficiency of iodine in the gland. Some experimenters lately had observed that if the mother dog had iodine completely withheld from the food the puppies would have goitre. It had been known, of course, for a long time that iodine was a good thing for goitre, but up to now that knowledge had been empirical and ill understood. As a result of observations on men and animals in all parts of the world, particularly in France, Switzerland, and the United States, where goitre was prevalent, an attempt was being made completely to eradicate the disease by ensuring that food contained a minute amount of iodine. If this combined study of man and animals proved as successful as was expected, it would lead to the extinction of simple goitre both in animals and in man, and with goitre would go the allied disease of cretinism. In the new Section human and veterinary medicine were equally represented, and the Society had been fortunate enough to secure for the first Sectional President, Sir Clifford Allbutt.

#### *The Church, the State, and the Law.*

Dr. HERBERT WILLIAMSON, in proposing the toast of "The Guests," said that the Society welcomed that evening the Archbishop of Canterbury, representing the Church, Sir William Joynson-Hicks, representing the State, and Lord Haldane of Cloan, representing the Law. Church, State, and Law were all inextricably woven in the history of Medicine. It was right that His Grace of Canterbury should be at their board, not only because of the dignity and wisdom with which he himself had filled his great office for twenty years, but because from the earliest dawn of civilization medicine and religion had been closely associated. It might justly be claimed that medicine had always respected the prerogatives of religion, though the Church had not always respected the prerogatives of medicine. The sick poor in the hospitals had found in the clergymen their warmest friends, and the Society welcomed the Archbishop because of the debt which medicine owed to the Church, because of the common service which united the two callings, and because of the universal esteem which the Archbishop had won for himself. Sir William Joynson-Hicks, before coming to his present position, gained great success as the head of the Post Office. A Minister of Health should possess

many qualities, including the courage of a Daniel: he must be something of a poet and a philosopher, and above all a lover of humanity, possessed of wisdom and understanding, able to dream dreams and see visions, and to translate them into action. It was difficult to discover a man who united all these qualities, unless indeed a search was made for him in the medical profession! He took advantage of the fact that the Minister that evening was unaccompanied by his permanent officials, and pleaded for a more liberal endowment of medical research and education. Lord Haldane was one of those coveted mortals who had attained distinction in many diverse fields of learning and administration. As statesman, philosopher, scholar, and lawyer, his great gifts had been placed unreservedly at the service of his fellows. He had never allowed party loyalty to deflect him from the path which he believed to be right, and he wore the Order of Merit, which was a distinction for all time.

LORD HALDANE said that it fell to him to try to convey a layman's sense of gratitude to the medical profession. The most valuable thing that the medical profession had taught the community was that people were their own enemies and that if they would but trust to Nature and not hinder her all would be well. He was an old conservative, and he looked back to Hippocrates, a man who understood thoroughly what life meant, and that if matters were left to life and to Nature, life and Nature would deliver us. Since the time of Hippocrates there had been only one other individual, and he a representative one, whom he had regarded with the same kind of admiration—namely, the old Victorian general practitioner, particularly the country practitioner of his own earlier days. This general practitioner was a splendid person even if he did not know very much and if his remedies were rough. Lord Haldane had known representatives of that class set out on their rounds in the islands of Scotland, without knowing in the least what demands would be made on their resources, but ready in the course of their visits from island to island to cut off a leg, or extract a tooth, or perform an operation for appendicitis. What the results were he never knew, but they were very useful people. To-day, however, there was a new atmosphere. They had learned to have faith that life and Nature would assert themselves if only the hindrances to their operations were removed. Surgeons discovered this perhaps even earlier than physicians. They learned that it was not necessary to resort to antiseptics, but that asepsis was enough—that is to say, if Nature were allowed to be unembarrassed she would assert herself and restore the equilibrium. That seemed to be the line which medical opinion was following. The President had mentioned the thyroid gland: he might have spoken also of the islands of Langerhans; these were bodies full of vitality and creative power if their stimulating processes were not defeated through lack of knowledge on our own part. A time had been reached when medicine was entering upon an entirely new phase. He looked forward to the day when, with very small provocation, he would go, not into a dismal nursing home, with no books or comforts, but into a gay establishment, which would be set up as a result of the combination of the instincts of science and commerce. They were grateful to the medical profession, not because it could avert death eventually, but because it succeeded in postponing death and warding off its unnecessary surprises for as long as possible.

SIR W. JOYNSON-HICKS, who also responded, said it would have been more appropriate if the doctors had invited him to dinner when he had control of the Treasury. But he was there to express his gratitude for favours to come from the great medical bodies on whom he must depend. The Minister of Health was really a creation of the doctors. It was on account of the demand so incessantly made by various members of the medical profession that he continued in existence. He had numerous requests made to him for more money to be spent on research, for improvements in medical education, for the extension of hospitals, for the eradication of epidemics, and his duties extended not only to the grave but beyond it, for it was part of his business to provide the medical profession with the necessary bodies for dissection. If the Minister of Health were himself a

Russell Andrews says and make a plea for mutual co-operation and support in a common task.

Let us both quit recriminations and recognize that the matter will appear different if looked at from a different standpoint. The first question we all have to ask ourselves is, are we satisfied with the maternity service of the country? Satisfaction with the present results can only be improved? There is no room for complacency, for our attention is constantly being directed to the failure to lessen the child-bed mortality and invalidity, the stillbirth rate and the neo-natal mortality (resulting largely from antenatal disease and prematurity and from complications in labour and birth injuries).

For its new lives the nation has to pay the price of labour and birth injuries. The price varies from year to year, but there has been no striking or permanent fall; in the last ten years it has varied from a lowest of one mother for 252 (in 1918) to a highest of one mother to 243 births (in 1919 and 1920). Contrast these figures with the remarkable drop in the infantile mortality rate, which, after being almost stationary for many years, has been halved in the course of the twenty-two years of this century. Surely the death of one mother for 500 or 1,000 births would be a heavy enough price for the natural function of reproduction, the greater part of the mortality of which is preventable—if so, why is it not prevented?

Once it is recognized that all is not well with our maternity service, the next step is to put our heads together to remedy it, and to obtain a diminution in the maternity figures equivalent to that obtained in infantile mortality. The experience is required of officers of maternity hospitals and gynaecological departments, of research workers, and medical officers of health, and of those practitioners with knowledge of the conditions under which domestic industry is conducted and of how these conditions can be improved. If this correspondence can pass from girding at teachers and specialists to some constructive proposals as to what can be done to forward this overdue betterment of our maternity statistics, it would be the best possible augury for the future.—I am, etc.,

JOHN S. FARMAN, M.D.

London, W., Dec. 15th.

#### SANITATION IN INDIA.

Sir,—In your issue of November 17th (p. 933), in a note under the above title, you refer to Mr. Russell's *Sanitary Handbook for India*, which has been brought up to date by Major A. J. H. Russell, I.M.S., Director of Public Health with the Government of Madras. You commend to notice a "valuable suggestion, applicable to other countries besides India, is that the rudiments of hygiene should be taught in all elementary schools." The usual necessity for economy of space in editing a new edition of a book probably prevented Major Russell from calling attention to the fact that this desirable requirement has long been fulfilled in at least one portion (143,000 square miles) of India—namely, the Madras Presidency. In 1879 the Government of India bestowed itself on the subject by offering an honorarium for "the best English elementary hygiene," I believe that Surgeon-Major J. A. Loring, I.M.S., then Inspector of Vaccination, subsequently officially suggested adoption of the subject in schools in the Madras Presidency. The Director of Public Instruction, in his letter 3491 of 1914, states that that "it had not been rendered compulsory, but is, as a hygiene was taught in schools 'apparently before 1820,' Madras Presidency. The Director of Public Instruction, in his letter 3491 of 1914, states that the matter of fact, generally taught in elementary schools to-day, apart from specific pamphlets for information and instruction in the unhygienic influence, for example, of filth, malaria, etc." Whilst it was not feasible for the Director to state, without special inquiry, the total number of many thousands of scholars attending these schools who had formally accepted instruction in the subject, he added that between 1883 and 1914, 2,755 and 1,876 appeared for the elementary and intermediate grade examinations respectively under the Government technical education scheme.

#### THE NERVOUS CHILD.

Colonel I.M.S. (ret.),  
W. G. KIRK,  
London, N.W., Dec. 15th.

Sir,—Many years of observation have convinced me that, while there are doubtless predisposing factors in the quality of tissue inherited by the type of nervous child depicted by Dr. Cameron (November 24th, p. 963), the first exciting cause is usually disturbance in the character and distribution of the intestinal flora; its exact nature has been studied by Herter and other pathologists. Clinically, its commonest manifestation is chronic gastro-intestinal catarrh with recurrent febrile exacerbations, but all the mucous membranes of the body are apt to be affected. In other words, this type of nervous instability is a graft on the "catarrhal diathesis," Dr. Cameron duly notes this association, but the special opportunities of a family doctor have enabled me to observe that the order of precedence is invariable—the catarrh comes first. There appear to be two proximate causes of this catarrhal disposition. First, the excessive ingestion of carbohydrates; secondly, exposure to damp (especially by living on damp soils) of children whose family or racial antecedents underwent evolution under drier conditions. Examples I would quote are blonds, Jews, or derivatives of undisturbed rural communities long-settled on permeable subsoils—for example, the new and old red sandstones of Devon. These and others of the kind seem to lack resistance to the infection of mucous membranes on the heavy clay soils that serve for many urban sites or when they reside in river valleys or other humid districts. The immediate result of the engorged catarrh is the absorption of toxins causing, among other symptoms, a general muscular lability. In these circumstances the child's heavy head cannot be held well poised on the spine—it tends to tilt forward, causing the spine to curve and the shoulders to droop. To compensate for this the pelvis is swung forward in its turn, and the result is the stance described and illustrated by Dr. Cameron. By the time this unfortunate state of disturbed digestive functions, malnutrition, toxic absorption, endocrine perversion, and muscular hypotonus is established the child usually finds itself immersed in the atmosphere of perpetual concern, remonstrance and exhortation so well set forth by Dr. Cameron. Even if the parents are wise and the family history sound, the child may find itself in a condition of nervous tension through its efforts, despite fatigue, to please them or emulate other and healthier children. There is therefore small cause to wonder that psychic maladjustments are added to the other troubles.

Satisfactory treatment of these cases is often very difficult because of the other troubles. The Government technical education scheme, especially under the Government technical education scheme, has long been fulfilled in at least one portion (143,000 square miles) of India—namely, the Madras Presidency. In 1879 the Government of India bestowed itself on the subject by offering an honorarium for "the best English elementary hygiene," I believe that Surgeon-Major J. A. Loring, I.M.S., then Inspector of Vaccination, subsequently officially suggested adoption of the subject in schools in the Madras Presidency. The Director of Public Instruction, in his letter 3491 of 1914, states that that "it had not been rendered compulsory, but is, as a hygiene was taught in schools 'apparently before 1820,' Madras Presidency. The Director of Public Instruction, in his letter 3491 of 1914, states that the matter of fact, generally taught in elementary schools to-day, apart from specific pamphlets for information and instruction in the unhygienic influence, for example, of filth, malaria, etc." Whilst it was not feasible for the Director to state, without special inquiry, the total number of many thousands of scholars attending these schools who had formally accepted instruction in the subject, he added that between 1883 and 1914, 2,755 and 1,876 appeared for the elementary and intermediate grade examinations respectively under the Government technical education scheme.

Press statements referring to the recent adoption of medical inspection of schools in the Madras City, where (in virtue of an *imperium in imperio* policy) sanitary advance has notoriously lagged, have rendered it possible to conceive that this also is an innovation in India. This is not the case. In the Madras Presidency sanitary inspection of all schools and colleges supported or aided by Government or public bodies was, to my personal knowledge, a well accomplished routine duty of district medical officers from 1886 to 1905, and presumably is so—with modification as to staffs—up to date. This valuable method was sanctioned by the Madras Government on the advice of the late Surgeon-General Bidie, C.I.E. A similar misapprehension has attended the tardy introduction by the Corporation of Madras of placing at disposal of the public the attendance of qualified midwives, following an order of the Madras Government in 1882. Midwives for public and private practice have been educated and afforded certificates of qualification after examination. Outside the Madras City limits both municipalities and district boards have utilized them freely. With some self-gratulation the Corporation within the last three years has started a baby welfare scheme. Yet the Government of Madras (referring to the recommendation of their sanitary commissioner of 1905) urged its adoption in 1906, in the presence of great infantile mortality. The Corporation of this large city in sanitary matters "hasten slowly."—I am, etc.,

medical man it was possible that he would spend too much money on a particular branch in which he happened to be interested. It was his business to judge between the various claims, with due regard to the attenuated state of the public purse, and to prepare the claims in such a way that they might be understandable to that remarkably non-scientific body, the House of Commons. It was to the Fellows of the Society that he looked for advice. The Society was a thoroughly independent body, free from State control. It had no irritating political questions to trouble it. He looked to it for advice and encouragement, and for consolation in his failures. The office of the Minister of Health was the most difficult that he had ever filled, and if to its responsibilities was added, as the President rather suggested, the medical care of animals, he would indeed have no peace. The situation with regard to foot-and-mouth disease was a very grave one. The number of animals now being slaughtered every day on account of this pest represented a value of £70,000. He was a member of a committee of the Cabinet appointed that day to deal with the question, and he would be very grateful for any help which could be given him by the medical profession which might assist in the control and prevention of this scourge.

The proceedings of the dinner were over at the commendably early hour of 10.30.

### THE GENERAL ELECTION.

#### MEDICAL MEMBERS OF THE NEW PARLIAMENT.

The following five medical men who were members of the last Parliament have been returned to the House of Commons at the recent general election:

Sir GEORGE BERRY, LL.D., F.R.C.S.Ed. (C.), Scottish Universities; returned unopposed.

Dr. W. A. CHAPPLE (L.), Dumfries. Majority 1,727 on a total poll of 24,487.

Dr. F. E. FREMANTLE, O.B.E. (C.), St. Albans. Majority 5,328 on a total poll of 25,077.

Sir SYDNEY RUSSELL-WELLS, M.D. (C.), University of London. Majority 1,444 on a total poll of 8,050.

Dr. J. H. WILLIAMS (Lab.), Llanelli. Majority 9,298 on a total poll of 38,270.

Three medical men who sat in the last Parliament did not seek re-election—namely, Sir John Collio, C.M.G., Dr. L. G. S. Molloy, D.S.O., and Sir William Whitla; another, Mr. C. Harvey-Dixon, died on September 22nd, 1923.

#### New Members.

The following five members of the medical profession have been elected to Parliament for the first time:

Dr. L. HADEN GUEST (Lab.), Southwark North. Majority 362 on a total poll of 14,968.

Dr. Haden Guest was an unsuccessful candidate in the general election of 1922. He was a civil surgeon in the South African war. During the late war he held various posts in connexion with the British Red Cross and the Croix Rouge Française; he served also in the R.A.M.C. with the rank of Major, and won the Military Cross. He acted as secretary and medical adviser to the delegation to Soviet Russia in 1920, and among other writings on medico-sociological subjects lately contributed a series of articles on "Public Health in Soviet Russia" to the BRITISH MEDICAL JOURNAL.

Mr. SOMERVILLE HASTINGS, F.R.C.S. (Lab.), Reading. Majority 1,542 on a total poll of 37,178.

Mr. Somerville Hastings stood unsuccessfully for Epsom at the 1922 election. He is surgeon in charge of the ear and throat department of the Middlesex Hospital and lecturer on diseases of the ear, throat, and nose at the Middlesex Hospital Medical School. He was a vice-president of the Section of Laryngology and Otology at the last Annual Meeting of the British Medical Association. He is a member of the Public Health Advisory Committee of the Labour Party, and has been a prominent advocate of a State Medical Service.

Professor THOMAS SINCLAIR, C.B., F.R.C.S. (C.), Queen's University, Belfast; returned unopposed.

Professor Sinclair is a Senator of the Parliament of Northern Ireland; surgeon to the Belfast Royal Hospital; professor of surgery in Queen's University, Belfast, and a

member of the General Medical Council. He served during the war as consulting surgeon to the British Expeditionary Force with the rank of Temporary Colonel A.M.S., and is a past-president of the North of Ireland Branch of the British Medical Association.

Dr. G. E. SPERO (L.), Stoke Newington. Majority 1,101 on a total poll of 15,629.

Dr. G. E. Spero was an unsuccessful candidate for West Leicester at the 1922 election. He qualified in 1919, having previously served in the Navy. He is a member of the Leicester and Rutland Division of the British Medical Association.

Lieut.-Colonel T. S. BEAUCHAMP WILLIAMS (Lab.), Kennington. Majority 510 on a total poll of 21,149.

Colonel Beauchamp Williams is a retired officer of the Indian Medical Service, in which he served for twenty years. During the late war he was on active service on the North-West Frontier and in Mesopotamia. He is a member of the Executive of the Westminster and Holborn Division of the British Medical Association.

At the general election in November, 1922, there were 35 medical candidates, of whom 13 secured election. At the general election on December 6th, 1923, there were 25 medical candidates, of whom 10 have been returned to Parliament. Besides these ten medical men, two valued members of the Medical Committee of the late House of Commons have been re-elected. Sir Henry Craik was returned unopposed for the combined Scottish Universities, and Sir Martin Conway was returned at the head of the poll for the combined English Universities.

#### Unsuccessful Candidates.

We regret to record that four medical men who sat in the last Parliament were defeated at the polls—namely, Dr. Walter Elliot, M.C. (C.), Parliamentary Under Secretary for Health for Scotland, who had represented Lanark since December, 1918; Dr. J. E. Molson (C.), who represented Gainsborough during the same period; Dr. Alfred Salter (Lab.), who was elected for Bermondsey West in 1922; and Dr. Thomas Watts (C.), who was elected for the Wittington Division of Manchester in 1922.

The following members of the medical profession were also unsuccessful; several of them had previously contested either the same or other constituencies:

Dr. H. B. Bates (C.), Newton, Lancs.  
Dr. Ethel Bentham (Lab.), Islington East.  
Dr. R. Dunstan (Lab.), Birmingham, Ladywood.  
Dr. O. Gleeson (Lab.), Portsmouth North.  
Dr. G. B. Hillman (C.), Normanton.  
Sir Henry Lunn (L.), Brighton.  
Dr. H. B. Morgan (Lab.), Camberwell North-West.  
Dr. A. G. Newell (L.), Tottenham South.  
Lieut.-Colonel A. C. Osburn, D.S.O., R.A.M.C.(ret.) (Lab.), Walsall.

Dr. R. W. Simpson (L.), Newcastle-upon-Tyne North.  
Dr. R. M. Wilson (L.), Saffron Walden.

[Dr. R. L. Ridge, whose name appeared in the list of medical candidates in our issue of December 1st, did not contest the Enfield Division.]

#### Polling Figures.

The following are the polling figures at all the contested elections in which there were medical candidates on December 6th. Medical names are printed in italics, and an asterisk denotes that the candidate sat in the late Parliament.

the bladder muscle failing to contract.

If this is the case in a healthy bladder a negative pressure then exists within the bladder

the bladder is kept on a lower level than air cannot enter.

The presence of air in the bladder gives rise to the growth of certain bac-

terial growths, the result of catheterization is common and everyone will recall how rapidly urine under-

line decomposition in warm weather. It would appear to be more satisfactory to empty the

siphonage than by expression. This can easily be accomplished by the recumbent position by attaching a foot or

rubber tubing to the end of the catheter and letting it run over the side of the bed. It is necessary, however,

the bladder wall by suction, and so become ob-

and the nervous and psychoses that accompany these woe-

Embarked for this and a more general growth of pathogenic

organisms at the portal of the respiratory and digestive

tracts and greatly aggravate the whole condition, but they

are a result and not a cause of the catarrhal state. Re-

movable in correcting the faulty posture, flat-foot, etc.,

but their utility is much limited unless the defects of the

environment are adjusted.

A thorough understanding of child psychology and psycho-

therapy is also needed, for the "sense of inferiority," is all

too readily acquired, as are also the various "fixations," and

"complexes" that impede or pervert psychic development.

The root of the matter appears to me to be that the

simple traditions and crude eugenics that served our fore-

fathers, and for guidance in the rearing of

children no longer suffice us. They were all very well in the

days when families were large and the devil took the hind-

most, or when generation after generation had bred in the

same environment and effected stable adjustments by cumu-

lative acquisitions of mother-wit. We are dealing largely

now with the huge, floating, heterogeneous populations of

the industrial era, and new and more complex traditions

must be devised to meet the needs of a more complex civiliza-

tion and to give the individual a better chance of satis-

factory adjustment to his environment.—I am, etc.,

M.D., M.R.C.S., L.R.C.P.

Hampstead, Nov. 29th.

HYPOGLYCAEMIA AND EPILEPSY.

Sir,—The use of insulin in the treatment of diabetes

signs and symptoms of an ordinary epileptic seizure lead

me to ask whether we have not here, perhaps, some clue

to the cause of epilepsy itself.

It would appear that it is the hypoglycaemia induced

by an overdose of insulin which is the causative factor in

the epileptiform attack, for insulin does not appear to have

any other pronounced effect on the blood stream. At

least there is no evidence that it produces either an

anaemia or a hyperaemia of the brain. It is, at least,

a possibility, therefore, that it is the reduction of the

blood sugar below a certain percentage that produces

the epileptiform seizure. If this be so, one feels justified

in asking whether the cause of true epilepsy may not

yet be found to be either a persistent or a recurring

hypoglycaemia. I am carrying out some observations in a

small way, but investigating by one engaged in general

practice is necessarily difficult. I would suggest for those

along the following lines will at least prove of interest.

(1) Does the examination of the epileptic during a

normal state of health reveal any abnormality in the per-

centage of blood sugar—for example, is there a tendency

normally towards a hypoglycaemia?

(2) During the seizure itself is there any evidence of

a hypoglycaemia?

(3) Does autopsy reveal any abnormality of pancreas—

for example, hypertrophy of the islands of Langerhans; or

does it show any atrophy of other antagonistic glands?—

I am, etc.,

Whitehaven, Nov. 21th.

J. W. MACRAE.

ATTITUDE IN CATHERIZATION OF THE

BLADDER.

Sir,—I am inclined to think that the answer Dr. Bamford

gives to the question he asks (November 17th, p. 947) is

not quite complete.

I have noticed repeatedly in passing a glass catheter in

the bladder.

Supravaginal hysterectomy

PANHYSTERECTOMY.

Sir,—I opened this week's Journal in the fi-

tion of finding a letter from Dr. Herbert Spencer

above subject, nor was I disappointed. I think

## Nova et Vetera.

### NATIVE MEDICINE AND HYGIENE IN SINGAPORE.

INSPECTOR KING of the Sepoy Lines Police Station, Singapore, informed me one day that recently on a gambling raid—the Chinese and Malays are inveterate gamblers—he had seen two peculiar skulls. Inquiry had elicited the fact that they were very old Labuan skulls which had been handed down from father to son for several generations.

One evening in the golden glow of the setting sun Inspector King escorted me over a hill studded with the graves of departed Chinese. The Chinese are imbued with a spirit of reverence and veneration for their parents and ancestors. The ambition of the average Chinese is to have a large family to support him in comfort in his old age, and for this purpose he may acquire several wives; or he may purchase a few boys and adopt them as his sons. The Chinese bury their relatives on the summits of the highest hills in the vicinity, never omitting to place a dish containing some food at the graveside, lest the spirit of the departed should revisit the place of interment and be in need of sustenance for its gossamer substance. Having settled their ancestors, the mourners descend to the swamps and valleys, there to live huddled together in large numbers, an easy prey for all infective diseases, especially tuberculosis. Having reached the foot of the burial hill, we traversed a clearing in the jungle honoured by the name of road. Here we had an indication of European influence in a concrete trough about two feet in depth and width, which acted as a drain; filthy water laden with sewage slowly flowed along it, and lying in it were two putrefying young pigs. Following the road we came to a large fruit, flower, and vegetable garden owned by Chinese. The gardens were beautifully kept. Being evening, the gardeners were busy watering the flowers and vegetables. The drain was convenient; the material in it was wet, and also provided a certain amount of manure; the vegetables grew well in consequence. Can we wonder, then, at the prevalence of enteric, dysentery, and *Ascaris lumbricoides*? At least 90 per cent. of the native children are infested with the latter. It is a common incident for a child in a fit of coughing to expel from the mouth one or more worms five or six inches in length. A water-borne sewage scheme was commenced in Singapore some time ago, but will not be completed for a considerable period.

Eventually we arrived at a native house of the variety common in this locality: a wooden structure surrounded by domestic refuse of all sorts in which mosquitos breed. The roof is made rain-tight by a thatch made in lengths of about three feet from the dried leaves of the banana tree folded across a light strip of bamboo. To gain admittance to the house we carefully stepped over innumerable chickens of varying ages and avoided a goat tied to one of the doorposts; a sow and her litter of young pigs were browsing close by. The house consisted of two apartments each about twelve feet square. The one nearer the door was used as a living room; the other, separated by an incomplete partition, was apparently a bedroom. In a warm country soft beds are neither comfortable nor desirable. The natives mostly sleep on a flat wooden structure raised from the ground on trestles and for a pillow use a wooden or porcelain block placed behind the neck. The room of which I write contained a structure about twelve feet by eight, covered with floorcloth. There were numerous such pillows lying about, so that this bed was presumably common to the whole family. It is difficult to estimate the number of a native family, for so long as there is a spare corner they do not hesitate to take in a few lodgers. Present in the house at the time, however, were the old doctor, two young men, three women, and several children.

Our arrival caused a little excitement, but on being informed of the peaceful nature of our visit the inmates were friendly towards us. We were shown into the bedroom, and the old doctor lifted the two skulls from their resting place—a wooden box the bottom of which was nailed to the wall to form a small cupboard, while two pieces of cloth

Obituary.

SIR FREDERICK TREVES, Bt., G.C.V.O., F.R.C.S., Consulting Surgeon to the King; Consulting Surgeon, London Hospital.

THE death of Sir Frederick Treves on December 7th will come as a surprise to his many friends. He had passed through a severe attack of pneumonia last year, but seemed to have recovered. He had lived for some time in Switzerland at Evian, on the Savoy side of the Lake of Geneva. In the autumn he moved to Vevey, on the Swiss side, where he had just established himself in a flat when he was taken on December 3rd; his death, which was due to peritonitis, occurred a nursing home at

Frederick, the son of

William Treves of Dor-

chester, who married

his daughter of John

in February 18th,

his early education

was received at Merchant

Navies' School; after

studying at University

College, he entered the

London Hospital. He

obtained the diploma of L.S.A.

in 1874, and passed the

following year. After

holding the post of resi-

dent assistant surgeon to

the Royal National Hos-

pital for Scrophulous (as it

was then called) at Marl-

gate, and filling several

senior resident posts at

the London Hospital, he,

in 1877, began general

practice in Warwick,

where, in partnership

with Dr. William Mill-

ingham, he passed the final

R.C.S. examination in

1878, and in 1879 was

appointed surgical regis-

trar and assistant surgeon

at the London Hospital,

where he also clinical assistant

in physiology as well. He

acted as demonstrator in

anatomy and succeeded Mr. Rivington as head of the

anatomical anatomy until 1883, when he became full

professor. The light of his inquiring, original,

and observing mind was not one to be hidden under

the bush, and he soon attracted notice as a surgeon and

a teacher of anatomy in a much wider field than his

hospital. He gave the Erasmus Wilson lectures in

anatomy at the Royal College of Surgeons in 1881. Two

years later he published his epoch-making work on surgical

applied anatomy, and gained the Jacksonian prize of the

College for an essay on intestinal obstruction.

When Treves was appointed assistant surgeon to the

(By the courtesy of the Secretary of the London Hospital Medical College.)  
WILSON LECTURE TO THE LONDON HOSPITAL  
FREDERICK TREVES.  
Engraving by J. E. Hill and Co.

he had a large share in placing this department of surgery on a sound basis. In 1885 he was Hunterian Professor of anatomy in the Royal College of Surgeons and delivered four lectures on the anatomy of the intestinal canal and peritonitis in the following year. The lectures were based on a careful examination of 100 bodies, and the result of his researches was that many theories and statements then commonly found in textbooks were badly shaken. In the nineties Treves was the best known and most successful of London surgeons and his success was due to a variety of causes. In his systematic lectures on anatomy and (later on) surgery, he was an impressive teacher, who at the same time interested his class and maintained discipline. Few men worked harder at his public and professional duties than he. Until his private practice became very extensive he regularly attended the hospital on Sundays to examine the cases in his wards more thoroughly and at greater leisure than he could wish. An immense following of students and visitors from all parts of the world, and he would then go for a forty or fifty miles' cycle ride. With the students he was always immensely popular, and for many reasons, an athlete himself and a certified master-manner, he could excel them in nearly any feat on land or sea. They recognized his ability, surgical skill, and above all his extraordinary powers of work and virility. The portrait we reproduce by the courtesy of the Secretary of the London Hospital Medical School shows him at this stage of his career. He was at the head of every meeting and movement of the students, and was the main instrument in affixing all the students' clubs into a Students' Union, of which he was appropriately the first president. A man of such powers naturally had a commanding voice in the management of the medical school, and for nearly twenty years was a member of the College Board. Hard work alone will not command success, but in Treves it was combined with a quality of trustworthiness and steadfastness resting on the true self-reliance of knowledge and experience. Those who observed him in the wards of the hospital, at an operation of difficulty or danger, or at a "sing-song" of medical students, never saw him embarrassed or ill at ease. A sense of humor, rarely absent in those who rise to eminence, the power of public speaking associated with a happy and picturesque turn of phrase and word, always placed him in sympathy with his audience, whether at a scientific meeting, a dinner, or at a student-gathering. Commanding such widespread confidence, his appointment to be a civilian consulting surgeon in the Boer war (1899) gave great satisfaction. In previous Continental wars

hung as curtains in front. I examined the skulls carefully while the old man squatted on the bed. They were typical negroid skulls of adult males, old but not ancient. The base of each was entirely missing, as also were parts of the vault. The only feature worthy of note was the persistence of the metopic suture in both skulls in its entire extent. The skulls were marked all over by fine scratches as though they had been filed, and the alveolar process of each superior maxilla had been entirely filed away; when the Inspector asked why, they replied that the filings were used for curing all forms of gland swellings, including those specially classed as bubos, and the medicine man proceeded to explain his methods. A small biscuit box filled with grass was produced, and from it the old man drew a centipede about nine inches long, three-quarters of an inch in diameter, and of a brownish colour. It was quite harmless, and he allowed it to crawl about on his hand and arm. The centipede is eventually charred in the fire, its ashes carefully collected and ground into a fine powder in a mortar and pestle. The powder is then transferred to a small glass bottle and is ready for use. The skull is filed by means of a piece of skin from the dorsum of a shark dried in the sun to form a cylinder about fifteen inches long. The placoid scales with their enamel tips are admirably suited for grating down the bone.

In the treatment of tuberculous or other gland swellings the skin is washed to remove any sebaceous secretion. A small quantity of the skull gratings and of the charred centipede powder is added to some powder prepared from the root of the camphor tree and made into a paste with water. If the surface of the skin is broken hot water is used and the paste applied hot. If the surface is unbroken cold water is used and the mixture applied cold. In either case the applications must be made twice daily—at 7 a.m. and 4 p.m. To prove the efficacy of the treatment a small Chinese girl about 3 years of age was produced, much against her desire. On her neck there was a dirty sloughy-looking sore the result of a tuberculous gland, which the old man had been treating for three or four months. It was explained to us that the treatment was acting well in this case. Time, of course, is no object here, only the end-result counts. If by natural means and in spite of the treatment a sore is eventually cured it must be due to the treatment. This belief, of course, is not confined to the East. When asked if the native Chinese medicine men ever used a knife in treatment, the old man lifted up his hands and gazed at us in horror. Use a knife! A knife is only for killing with!

Let us now analyse the methods employed and compare them with those used in modern treatment. In both cases on the unbroken skin cold applications are used, and the medicine man, by means of his camphor, was using a mild counter-irritant and skin stimulant with slight antiseptic properties. When the skin is broken and ulcerated, modern and ancient methods agree in the value of heat. The Chinese uses the charred centipede simply as charcoal, which is well known for its deodorant and absorbent properties. The skull gratings are merely a collection of calcium salts of value for their soothing effect on the skin in itching, and for their astringent and desiccative properties. They are useful to promote healing in eczema and ulcers. Although antiseptics are unknown as such, yet it is practised by these old medicine men, whose knowledge is the result of the experience of generations. Asepsis is entirely unknown. One may ask, Why go to such trouble to obtain common materia medica? The answer I suggest is that throughout the whole world faith is one of the great factors in the art of healing, and faith with the natives is inexorably bound up with religion. Undoubtedly the methods employed are supposed to emanate from some deity.

We were now shown two powders invaluable in the treatment of skin diseases; equal quantities are infused with water and the infusion taken regularly over a long period. The powders were simply senna and a special brand of Siam tea. For dirty tongues there was a white powder, obviously borax, which is applied by the medicine man. He moistens his finger with saliva and dips it into the bottle, thereafter rubbing the powder over the patient's tongue. This treatment is combined with a course of powdered liquorice root internally. We had now to inspect a wonderful powder

which the medicine man explained with great pride was of great value in the treatment of pains in the female abdomen. It had no specific value in the male. So far as I could judge it was a preparation of hyoscyamus. For wind in the stomach he had a preparation of menthol and liquorice. The great sedative, however, for the Chinese is that maker of happy dreams—the opium pipe; the Government has wisely legalized its use and has licensed special shops for opium smoking. The incidence of venereal diseases is very high in Singapore and is not confined to the native population. Such a condition of affairs is inevitable in a community in which males greatly predominate, and especially in an international port like Singapore. If houses and women were licensed and regular inspections carried out the occurrence of venereal diseases would diminish.

The bottles containing the drugs were of various sizes and shapes and were unlabelled except where a label indicating a former content had withstood the ravages of time. Any preparation which was not distinctive in smell or colour was quickly analysed by the old man by the simple method of dipping his finger into the bottle and tasting the contents. He was very anxious that I should sample some of his preparations, but repulsion at the method of sampling employed was greater than my inherent curiosity, so I refrained. In addition to the cures for the diseases mentioned, he had remedies for fever in the form of ground cinchona bark, and for rheumatism, worms, and a few other diseases the nature of which I could not discover. His stock-in-trade was very small, about a dozen bottles in all, and this, I think, is one of the points in which modern medicine might follow his example with advantage by seriously reducing the number of official drugs in the *British Pharmacopoeia*.

College of Medicine, Singapore.

## THE REHOUSING OF SLUM DWELLERS.

THE problem of housing in relation to the health of the community is of such importance that it is a pity that a paper on the rehousing of slum dwellers<sup>1</sup> read by Mr. John J. Clarke at the meeting of the British Association last September should not have been written in a more concise, coherent, and interesting manner. It is not easy at first to gather the exact nature of his proposals for rehousing slum dwellers. In his introduction he says that "the solution of the problem is bound up with the payment of an equitable wage to meet the rent demanded," while in his chapter on Rehousing in the Future he says that "it must be remembered that unless the displaced poor are housed at a rent which is not an equitable rent, they will not be housed in a separate house at all." It is possible that Mr. Clarke felt the need of some restraint in setting forth before the British Association proposals decidedly socialistic in tendency; or peradventure he was afraid of the results of his own ideas. If, however, the housing problem is soluble at all, it may be that the only solution is to be found on the lines suggested in this paper. We shall endeavour to trace the sequence of Mr. Clarke's thoughts.

Slums reproduce all the defects with which a Public Health Department has to deal, and from the point of view of health and morals housing is the one essential reform. Overcrowding in slums leads to increased infant mortality, to impairment of health and unnecessary deaths of adults, to expense in connexion with doctors, nurses, hospitals, sanatoriums, and poor law institutions, to a low standard of morality, to increased cost in policing and cleansing and in the administration of justice, and to much waste of money in public houses. For more than sixty years local authorities had been fighting the housing difficulty, and just when the end of the first stage was in sight the war forced a halt. The problem is, in the words of Robert Browning, a "common problem, yours, mine, every one's"; and as such belongs to the realms of both ethics and economics.

<sup>1</sup> Some Factors relating to the Rehousing of Slum Dwellers. By John J. Clarke, read before the Economics and Statistics Section of the British Association for the Advancement of Science, Liverpool, 1922. The University Press of Liverpool, Ltd.; London: Hodder and Stoughton, 1922. 2s. net.

as soon as he could get in. which resulted in the relief of Ladysmith, which he visited and throughout the comparatively prolonged operations attached to Buller's army in Natal. As consulting surgeon 'Treves sailed for South Africa at the end of 1899 and was the Royal College of Surgeons, Mr. Treves, and Mr. Makins, the assistance of Sir William MacCormac, then President of the letters to this Journal describing incidents from week to week. The book which was based on these letters contained a striking picture of the medical side of the war, all the more vivid and moving because of its simple and unpretentious character.

Many charges had been made in the public press about the inadequate care of the sick and wounded during the war, and a Royal Commission was sent to South Africa in 1900 to investigate and report on the charges. Its report issued early in 1901 showed that while most of the charges were not justified, the unexpected severity and duration of the war had thrown a strain on the Army Medical Service which it had not been able to stand as well as it had been expected. The Commission recommended certain changes, and the War Office subsequently appointed a committee to report on the reorganization of the Army Medical Service. Of this committee Treves, who had been created K.C.V.O. in 1901, for his services during the war, was a member. His recent personal experiences of army medical work were of the greatest service to the committee, which recommended certain changes; these were carried out. That they were judicious was proved when in 1914 the Royal Army Medical Corps was submitted to the supreme test of the great war.

Treves served successfully as Surgeon Extraordinary to Queen Victoria, Surgeon to King Edward VII (1901), Surgeon in Ordinary to George, Prince of Wales, and Surgeon to King George V. It was while holding the second of these appointments that the eyes of the Empire and of the whole world were directed on him during the anxious days of King Edward VII's sudden illness in June, 1902, on the eve of his Coronation. The sudden announcement at 10 o'clock on the morning of Tuesday, June 24th, that the coronation of the King, fixed for that week, was postponed through the necessity of an immediate and serious operation, fell like a bombshell on the nation, for the public generally thought that the King was quite well as he had been, apparently, going about as usual and had moved from Windsor to London the day before. It soon became known that the operation was for the relief of an abscess about the appendix, and when it was further known that Treves was to undertake it the national alarm was greatly calmed. In an hour or so it was further announced that the operation had been successfully performed and that the King was doing well. It was not until some days afterwards (July 5th, 1902) that we were able in the Journal to give an explanation of the suddenness of the illness and the need of the operative treatment. It was then seen that the King had been suffering from June 15th from abdominal pains, but that he had kept up and filled important engagements in the hope that the symptoms would pass off and that the Coronation would not be interfered with. It was recognized from the first by Sir Francis Taking and Sir Thomas Barlow that the appendix was the cause of the trouble, and Treves was called in on June 18th. The King was most anxious that the Coronation should take place on the appointed day, and held on in spite of the uncompromising advice Treves gave as a surgeon. The symptoms subsided somewhat and the King was able to travel to London on June 21st, but that evening the swelling in the right iliac fossa reappeared in more marked form and the temperature, which had been normal for two or three days, suddenly rose. On Tuesday morning Lord

The first of his many works was published in 1861, *Treves* was a voluminous writer from his early years more. It was necessary to leave two large drains in the abscess cavity, but convalescence was unimpeded. Attached to Buller's army in Natal, as consulting surgeon and throughout the comparatively prolonged operations which resulted in the relief of Ladysmith, which he visited

On Tuesday morning Lord

His book on *Intestinal Obstruction: its Varieties, Pathology, Diagnosis, and Treatment* was published in 1884. It was in substance the essay for Jacksonian prize was awarded by the Royal Surgeons in 1883. For book form it was entire and rewritten in some parts, and such new material was required to bring the work up to date and importance of this subject at the time of publication may be estimated by the fact that over two individuals were then dying every year in London from various forms of obstruction of the bowels, of hernia. It was also a subject which was but little understood from the clinical standpoint. This reason the classification of the different varieties of intestinal obstruction was based on pathological rather than clinical distinction. The work more welcome reception because intestinal surgery was more feared than understood, and it had a very able influence on the progress of abdominal surgery.

Before the war the vast majority of workmen's dwellings were provided by private enterprise in the ordinary course of business. On a smaller scale building was undertaken by building societies, friendly societies, trade unions, co-operative industrial societies, philanthropic societies, employers of labour, societies of public utility, and by local authorities. Unfortunately building houses for the working classes is not attractive as an investment, and the builder alleges that the rent which they command does not yield sufficient profit. In addition to financial difficulties there are other reasons which deter the private builder, such as the effect of the Finance Act of 1910; the increase in rates which it was difficult to pass on entirely to the householder; the rigidity of the Public Health and Local Acts; war restrictions, including the Increase of Rent and Mortgage Interest Restrictions Acts, which are still unrepealed.

For these reasons it seems to Mr. Clarke inevitable that the local authorities should step in to meet the apparent shortage, if only on the grounds of public health. He is optimistic enough to think that a large mass of present-day public health activities would have been obviated if the local authorities had housed the people. This they could have done under powers they have possessed for more than forty years, but have allowed to remain dormant.

In England and Wales there are nearly a million dwelling places which consist of not more than two rooms. At least 200,000 of these are so bereft of ordinary conveniences that they ought to be demolished. According to an investigation by the local authorities in 1919 the nation needed nearly a million new houses; and Dr. Christopher Addison, then Minister of Health, estimated the immediate need for working-class houses in England and Wales alone at 500,000. In many of the existing houses families of ten or twelve persons are occupying one or two rooms; and it has been impossible to obtain conviction for overcrowding in face of the abnormal shortage of houses. The overcrowding is aggravated by the tenants of the houses taking in lodgers, often at exorbitant rents which are obtainable because of the impossibility of finding accommodation elsewhere.

Various expedients have been made to meet the house shortage. Thus in 1918 the Ministry of Reconstruction proposed a scheme by which, after a term of years, the responsibility for any excessive cost would fall upon those who incurred it. This scheme was set aside in favour of a proposal that the State should bear all the loss beyond the proceeds of a penny rate. The defect of this proposal was that it offered no substantial incentive to economy on the part of the local authorities. In addition to this the provision of a large sum of money to enable the Ministry of Munitions to purchase building material seriously inflated prices and contributed to increase the cost of houses. Under the Housing and Town Planning Act in 1919 the Assisted Housing Scheme gave a considerable stimulus to housing. But it appears that on a moderate estimate there was a loss of £60 a house per annum, the difference between the outlay and the rent including the penny rate. Consequently it was decided in March, 1921, that localities should be rationed on the basis of 250,000 new houses, and that the position should be reviewed in June, 1922, in the light of costs and results to that date. Shortly afterwards Dr. Addison ceased to be Minister of Health, and in July, 1921, Sir Alfred Mond made a statement upon the housing policy, in the course of which he said that the obligation to provide new houses rested, not on the Treasury, but on the local authorities, and expressed the hope that in a year conditions in the building industry would be stabilized, and no further Government action would be required. Thus financial stringency entirely changed the policy of the Government.

In discussing the problem of housing finance, Mr. Clarke wisely says that "although there may be sound social reasons for putting into force regulations which will prevent the free monetary expression of the law of supply and demand, all such measures, whether for restricting or raising price, are economically unsound." The capital cost of the 176,000 houses built under the Housing Acts, 1919, will approach £160,000,000; and the annual charge to the Exchequer will be approximately £8,750,000 in the early years. Conse-

quently the Government, as representing the taxpayer, is compelled to insist upon as high a rent as possible. The high cost of these houses was due to the increased cost of labour and material; and the increase in the cost of labour seems to have been the more serious, since the percentage of labour costs to those of material rose from 50 before the war to 84 in 1920, and has descended only very gradually to 57 in 1923. At the same time the state of affairs in the matter of materials was bad enough, so that the Committee on Light Castings in 1919 reported that the association of manufacturers of such castings was restricting its output and retarding efficiency in order to keep up prices. The Committee described this course as contrary to the public interest. At the beginning of the present year a Committee was appointed by the Government to report on the extent to which in any case the price of building materials appeared to be unduly high by reason of the operation of any trade combination, trust, or agreement.

Notwithstanding his statement that interference with the law of supply and demand is economically unsound, Mr. Clarke is so much impressed by the results of the limited efforts in housing carried out by the Borough of Birkenhead, or else is so pessimistic as to the future of private enterprise in building, that he urges the Government to take prompt action. Of the 2,264 houses required in Birkenhead only about 450 will be completed under the Assisted Housing Scheme. But Mr. Clarke finds that the improved environment of the rehoused slum dwellers has undoubtedly had a beneficial effect on the character and health of the people, and that much improvement is noticed in the health of the children. For a time frequent visits by the sanitary inspector were necessary to get the people to adopt a better tone of living; but the help and advice of the inspector were gladly accepted. The indifferent or bad tenant finds himself required to live up to the standard of the other tenants; and a happy and contented home life gives a return greater than the monetary value.

In discussing next the future policy as to rehousing, the opinion is expressed that the first thing to do is to abolish the excess of State regulations under the Assisted Housing Scheme and to limit control; apparently this refers to control by the State of the activities of the local authorities, and not to the control by these authorities of the tenant. The suggestion made is that the local authority should take the subsidy, that it should use its existing officers—for example, town clerk, medical officer of health, and surveyor—and that the houses should be sold to the occupiers or others after erection, in order to relieve the local authority of the cost of maintenance. Nothing is said about the purchase price, so that it is not clear by whom the loss on the houses should be borne. In the next place, in order to prevent overcrowding, it is suggested that the medical officer of health should be empowered to require that all houses—no matter what the rent—should be reported to him whenever there is any subletting. Thirdly, any scheme of rehousing in the future must be linked up with the improvement of transport. It is useless to attempt to house some kinds of slum dweller at a great distance from their work. The problem differs in different localities, but Mr. Clarke thinks that in Liverpool a solution is to be found in transport on the surface and not by underground tubes. Fourthly, wherever possible the self-contained house is held to be the most desirable type to build. On sites where such houses would be wasteful, flats of six or eight floors are recommended, with lifts for passengers and goods, playgrounds on the roof, central heating, a café, and a social institute with a library.

Long before it became a political question exciting party strife this journal maintained that, the water supply of large towns having been put in order, housing was the most pressing public health problem, and that until it was tackled much of the expenditure of public health authorities was little wiser than that of the Winchester chapter which hid the yawning cracks in its cathedral with cement. The difficulty has always been rehousing; obviously it was useless to clear slums if the inhabitants were not rehoused, but allowed to crowd into another or to form a new slum a mile or two away.

Neither the Legislature nor the local authorities have found

He did not deal with the indications for operation, nor did he enter into the subtle questions, the anxious reasoning, the special "surgical" points, which he mentioned in the operating theatre. "Surgical" points were contained on a note but received no attention for the selection of the case. His responsibility for the procedure was provided by the literature of the subject.

The case was dealt with in each section of the book. The annual review which success among the senior students and the qualified practitioners, but it was too soon for portability and consequently he prepared from it a *Student's Handbook of Surgical Operations* (1863) for the use of students preparing for final examination as a handbook to assist them in carrying out operations and no dead body. Only the most essential and important operations were dealt with actual technical details of operative surgery were omitted, and he assumed that the reader knew his anatomy. There was no after-treatment, or description of instruments, and no mortality or operation result figures given in the book. Though popular met his *Surgical Anatomy*. Both these works were revised with the assistance of Jonathan Hutchinson, Junr., and published in second edition in 1903 and 1904 respectively. With so many interests outside his professional work

one to keep to the command of professional routine life any longer than he could help, and as he made a phenomenally large income even for a popular and successful surgeon he was able to retire from practice in the full tide of life, at the height of success, and with every facility at its brightest and best. Many men may have the desire to retire at 50 from active work, but few medical men have the means to do so. Treves did practically no private professional work after his operation on the king; he occupied himself by working for the public good, especially in army medical matters. He was a member of the Territorial Forces Advisory Council, chairman of the Executive Committee of the British Red Cross Society, and a member of the London Territorial Force Association, and he was also an honorary colonel in the R.A.M.C. (Wessex Division, and an honorary staff surgeon to the R.N. Volunteer Reserve. He was Lord Rector of the University of Aberdeen (1905-8), receiving its honorary LL.D. degree. He also received honorary degrees from several other universities. He served as an examiner in anatomy or surgery for several years at the Royal College of Surgeons and in Cambridge, Aberdeen, and Durham Universities.

With his love of the sea, his fondness of travel, and his freedom from professional ties, Treves was able to spend a good deal of his leisure time in visiting various and remote portions of the world, journeys which were chronicled in a series of books published over several years. These books were written from the outlook of the unspecialized traveller, of the man who merely seeks some where to go. Descriptions of incidents on the journey, impressions of many and varied experiences and scenes, travellers' gains from the smoke-rooms of liners and hospital clubs, and collations from specialized books in the countries visited are interspersed with sharp comments and humorous turns of fancy such as might be expected from one who could brighten the dullness of an anatomy-book by his thoughtful interest for the anatomical information of a boy who had been recently lurching on the

On the account of his visit to Palestine, Treves did not set out to write a new *Bohnen*, nor with his books of wider travel to enter into the world-painting that with Pierre Loti; he hardly even had the light touch of the surgeon with his "log" suggested so well the joys of a voyage to the languorous East. He wrote to amuse and occupy himself and to give pleasure to his many friends, and he succeeded well in these objects. The first of these

published in 1886. Thirty-five of the leading surgeons of surgery in Treatises by Various Authors day co-operated with Treves in writing this work, aimed at presenting a concise account of the leading principles of modern surgery. The three volumes were composed of papers which were concerned primarily with the clinical, physiological, and therapeutic aspects of the general principles were dealt with, not

[illegible]

complete remedy, though something has been done, and before the war it seemed just possible that the improvement in transport, and the building of more houses and flats by private enterprise, supplemented by philanthropy and municipal schemes, would at least prevent the evil from growing. This has not happened for the reasons enumerated by Mr. Clarke, and we read on to see what remedy he had to suggest, only to be grievously disappointed, for it amounts to industrial conscription.

He maintains that the latest attempt of Parliament to deal with the shortage by means of a subsidy under the Housing Act, 1923, is not economically sound. The subsidy of £6 a house for twenty years will not meet the loss. In the race between population and houses in industrial districts population is gaining rapidly; and if all available labour in the trade were at once put on to house building the shortage would not be overtaken for twenty years. But it is stated that the number of men engaged in the industry is only 60 per cent. of the number in 1911, and continues to decline. The attitude of the trade unions is not such as to encourage an influx of apprentices. Meanwhile, abnormal conditions of unemployment exist. On these premisses Mr. Clarke argues that the nation should organize a war upon insanitary slums. He desires that this should be done by recruiting into the Royal Engineers, as Housing Battalions, men between 18 and 25 who have done no work for twelve months and can give no evidence of any prospect of work. After a course of training the men should be drafted into a battalion ready for service, and be paid the trade union rate of wages. At the same time the Government should introduce a system of costings for the building trade as a whole.

The author of such a plan is practically compelled to urge that a scheme for building houses should be national. Mr. Clarke affirms that the country would save more than the cost of the scheme through the reduction that would be effected on expenditure on the prevention and treatment of disease, on the cleansing of streets and houses, and on policing and the administration of justice. He deplores, however, the fact that local authorities appear to discourage rather than to encourage the ownership of dwellings, and desires that the Small Dwellings Acquisition Act should cease to be optional. To enable tenants to purchase their houses he advocates the promotion of municipal banks, an enterprise which is said at present only to have been undertaken by the Corporation of Birmingham.

But as has been said, his main remedy is a form of industrial conscription, and this we cannot regard as a suggestion of any practical political importance. Mr. Clarke's paper must therefore be regarded rather as a restatement of the problem, with modern instances, than as a contribution of any immediate value to its solution.

### THE LISTER WARD, GLASGOW ROYAL INFIRMARY.

CONSIDERABLE amount of discussion has recently taken place regarding the possibility of preserving the ward in the Royal Infirmary of Glasgow in which Lister carried out his earliest experiments in antiseptic surgery. The buildings have been under gradual reconstruction for a number of years, and this ward was situated in the last portion of the institution to be rebuilt; the ground on which it stands is now required for the new out-patient department. Last week the managers finally decided by sixteen votes to seven to demolish this portion of the old infirmary buildings entirely. It had been strongly urged that the old walls might be retained (the ward being on the ground floor) and the new building superimposed, as a memento of Lord Lister and of the great work done during his Glasgow period (1865-69). The ward with its old fittings was an interesting survival of the early nineteenth century hospital, and its disappearance is regretted by many, including the French Academy of Medicine, as noted last week by the Paris correspondent of the *BRITISH MEDICAL JOURNAL*.

### GIFT TO EDINBURGH ROYAL INFIRMARY.

The late Miss Jessie Aitken of Glenberrie, Larbert, left the residue of her estate, estimated at between £40,000 and £50,000, to the Edinburgh Royal Infirmary. Two-thirds of this amount, it was stated, would be held as permanent capital. Other bequests were announced, and it was stated by the treasurer that the receipts during the past two weeks had amounted to £3,431. During the two previous weeks the receipts had been over £10,945.

### NEW WING FOR Ayr COUNTY HOSPITAL.

The new wing of the Ayr County Hospital has just been completed at a cost of £14,000, raised entirely by public subscriptions. It comprises a children's ward, male ward, eight rooms for private patients, as well as accommodation for nurses; being constructed of steel and concrete, it is regarded as fireproof. With this extension the hospital now has accommodation for 107 patients.

### DRUGS FOR NATIONAL INSURANCE PATIENTS.

At the quarterly meeting of the Edinburgh, Leith, and District Friendly Societies' Council held in Edinburgh, Dr. Matheson Cullen, of the Scottish Board of Health, in a paper on National Health Insurance, referred especially to the provision of drugs. The lecturer stated that there was a misapprehension in the minds of some persons that insured persons did not always receive an adequate amount of medicine or medicine of the best character. This impression probably arose from the fact that occasionally one heard of doctors being surcharged for what was known as excessive prescribing. Two misrepresentations in the public mind tended to continue this impression—first, that every disease must be treated by drugs, and, secondly, that every disease had its definite and appropriate remedy. In effect, however, many diseases were self-limiting, and with appropriate dieting, nursing, etc., drugs might be unnecessary. The insured person at present got every drug that was necessary for adequate treatment, often at a cost in excess of what he could himself pay. This was obvious from the fact that such a costly drug as insulin was being sanctioned and prescribed for insured persons for whom it was appropriate, and that for some such patients bills of £20 to £40 and more had been incurred in the course of a few months' treatment.

## Ireland.

### GENERAL MEDICAL COUNCIL IN THE IRISH FREE STATE.

THE action of the Minister of Local Government in suggesting a conference of the licensing bodies to consider the constitutional effects on the present Council of the establishment of Saorstát Éireann, has induced the Irish Medical Secretary to send a letter to the Minister of Local Government pointing out that as the general medical practitioners in the Free State were represented on the General Medical Council they should be invited to take part in the conference with the other bodies. In his reply the Minister stated that in confining the conference to the teaching and licensing bodies he had believed that these bodies were vitally concerned in any administrative action that might be decided on, but he would welcome a statement of the views of the Irish Medical Committee on the question of future arrangements for the control of the medical and dental professions; as regards the particular aspect of the subject with which the pending negotiations are concerned, the Minister is of opinion that it can be more conveniently considered by representatives of the bodies immediately concerned.

### SALARIES OF ARMAUGH POOR LAW MEDICAL OFFICERS.

In a recent letter to the Armagh Board of Guardians the Ministry of Home Affairs (Northern Ireland) stated that it had noted with regret that the guardians had declined to act on its suggestion to consider this question, and had evaded the matter by postponement. The Ministry did not wish to deal with the question without the co-operation of the guardians, and before taking further action urged on the Board the desirability of reviewing the salaries at the earliest possible date. After a lengthy discussion the

guardians decided to appoint a committee to consider a commencing salary for each dispensary district, and also how the difference between the initial amount and the present flat rate should be apportioned amongst the several medical officers, regard being had to the number of tickets in each district, as well as its area. The scale so arranged would do away with the Ministry's objection to a flat-rate salary.

## England and Wales.

### LONDON SCHOOL OF MEDICINE FOR WOMEN.

THE annual dinner of the London (Royal Free Hospital) School of Medicine for Women was held at the Savoy Hotel on December 6th, under the chairmanship of Sir Alan G. Anderson, K.B.E. The large company of more than 330 included Viscountess Rhonda, Sir Humphry Rolleston (President of the Royal College of Physicians), Dr. Mary Scharlieb, Lady Barrett, M.D., Miss Aldrich-Blake (Dean of the School), Mr. V. Warren Low, Mr. James Berry, Mr. Ernest Miles, Professor Winifred Cullis, Sir Walter Schröder, Lord Riddell, and Dr. May Thorne. The Chairman, in proposing "Prosperity to the School and Hospital," remarked on the great progress made in recent years by women in medicine, and gave an outline of the work of the two associated institutions during the past year, mentioning in particular the lamented death of Dr. Percy Saunders and the approaching retirement of Professor F. Ransom from the directorship of the Pharmacological Department. He detailed also various recent benefactors, and referred to the honours and distinctions gained by students during the year, not only in academic subjects but also in games. The health of the guests was proposed by Mr. Joseph Cuning (Senior Surgeon to the Royal Free Hospital), and responded to in a very amusing speech by Professor W. E. Dixon, F.R.S. (Reader in Pharmacology at the University of Cambridge). Professor Louise McLroy, in proposing the Chairman's health, spoke of Sir Alan Anderson's constant championship of women and his close connexion with medicine in the persons of his illustrious mother, the late Dr. Elizabeth Garrett Anderson, and his sister, Dr. Louisa Garrett Anderson.

### TREATMENT OF CRIPPLED CHILDREN IN LONDON.

At a meeting of the London County Council on December 4th a joint report of the Education and Public Health Committee was submitted of the action taken on reports made to the Council in 1921 and 1922 by Mr. R. C. Elmslie on a survey of physically defective children, and by Sir Henry Gauvain on the treatment of surgical cases of tuberculosis. The increase of in-patient accommodation for surgical tuberculosis among children was so considerable that it could now be described as adequate. The purposes to which the Council's grant to the Invald Children's Aid Association may be applied have been enlarged, and it may now be used for the supply of surgical instruments as part of the after-care of children who have received residential treatment in institutions of the Metropolitan Asylums Board and elsewhere, and for any other suitable cases of surgical tuberculosis from the Council's schools for the physically defective. The Metropolitan Asylums Board is seeking approval for the establishment of centres in London for the clinical after-care of children discharged from approved institutions, and the question of the after-treatment of cases of deformity of tuberculous origin is being investigated. The Ministry of Health is being approached by the Council with the object of determining the best steps to be taken to secure early diagnosis and early and efficient treatment of poliomyelitis.

### SMALL-POX IN THE METROPOLITAN AREA.

A case of small-pox has been reported this week at Wood Green, in the county of Middlesex. The patient had a mild and in some respects an anomalous attack. His infection was derived from Spain, where he had been on a visit. He ailed on his way home, and noticed spots on his face; it is

possible that he may have infected other people during the later portion of his journey. He arrived in England on December 7th. Every precaution has been taken to limit the spread of infection.

## Correspondence.

### SMOKING OF INDIAN HEMP AND OPIUM.

SIR,—In several recent issues of the JOURNAL reference has been made to the smoking of addiction drugs, particularly cannabis indica and opium. Some comments seem to me desirable.

I do not believe that active cannabis indica in a form suitable for smoking can be obtained in this country. Ganja and charas are readily obtainable from most of the wholesale houses, but they are inactive when smoked—that is, they contain little or none of the toxic red oil to which the action of hemp is due. Last year I tried every sample of ganja obtainable, and not one yielded an appreciable amount of active principle on smoking. This is not surprising, because cannabinol is very easily destroyed by exposure to air and light, and crude ganja in particular rapidly loses its activity. For Indian hemp to be really active it should be freshly picked on the Himalayas and sent in sealed tins to this country; the physiological activity of such material is a revelation to the European, though, as one of your correspondents rightly says, it has little place in therapeutics.

Smoking ganja or charas, as these are usually obtained in this country, has a very unpleasant effect, not distinguishable, indeed, from smoking any dried herbs such as coltsfoot, once in vogue as a harmless boy's tobacco, and due to the pyridine, collidine, and other volatile irritating substances given off. The first effect of smoking active hemp is an intense irritation of the throat, so intense and painful that the smoking is generally stopped; this irritation, as shown by salivation, cough, and expectoration, is one of the most characteristic features of the chronic hemp smoker in the East. For this reason it is common for the pipe smoker to draw the smoke through water; this diminishes though it does not stop the irritation. The effect on Europeans of smoking active hemp mixed with tobacco is to cause in a minute or two—that is, after four or five whiffs—a feeling of exhilaration which is particularly noticeable after mental or physical fatigue; if the inhalations are continued higher control is loosened, and the subject becomes talkative and often hilarious. In less than half an hour the whole effect is over.

The Royal Commission on Indian Hemp (1884) reported "that the moderate use of Indian hemp drugs produces no injurious effects on the mind," and again, speaking of these drugs, "the Commission are of opinion that their moderate use produces no moral injury whatever." Throughout the report the suggestion crops up, though I have not found it specially stated, that excessive indulgence is the result of a mind already diseased. The Ministry of Health to my mind were right not to include hemp in the Dangerous Drugs Act, since to do so is but to call attention to a drug which from the nature of things it is impossible to use as a drug of addiction in this country, and the action of which, except to a few experts, is unknown here.

A letter on opium smoking in your issue of June 23rd (p. 1076) by Dr. Maxwell contained a criticism on an address of my own before the Pharmaceutical Society. The principal features of this letter are his amazement that I should quote the findings of the Royal Commission on Opium of 1895 and my views on opium smoking. Perhaps I may make the position clear by pointing out that morphine and allied alkaloids, unlike nicotine and cannabinol, are not volatile, and when smoked as opium are largely destroyed; one analysis of the opium smoke from a great number I gave in the BRITISH MEDICAL JOURNAL for November 19th, 1921. When opium is smoked none of the bitter tastes of the alkaloids are perceived in the mouth. The total of morphine in one pipe is probably not more than 3 mg.—that is, if twenty pipes are smoked a day only 6 cg., which is about 1 grain, are smoked—and

of him! I have seen a good many strange and beautiful gardens, whether pitch dark or light, always at that hour, and never up later than 6 a.m., and as I take a "second Park," and the letter ends with this paragraph—

issued by the universities. The British Museum, as is well known, has the right to a copy of every publication issued in Great Britain, and the list now prepared reveals the important fact, hitherto not generally realized, that the National Library in the British Museum contains also the most extensive and representative series of foreign medical and scientific periodicals in Britain. "This," Professor Leiper says, "must strengthen the many centripetal circumstances now tending to make Bloomsbury in coming years the post-graduate centre of the Empire," a centre in which the British Medical Association is shortly to take its place when it enters into occupation of its new house, of which a picture was published last week (p. 33). Professor Leiper expresses his thanks to the Science Committee of the British Medical Association "for the lively interest it has sustained in a project which has occupied his spare moments for the past four years as well as for its generous guarantee whereby the labour of love of the compilers is placed in the hands of their fellow workers at a price based upon the actual cost of publication." The book will be published next week at the price of 10s. 6d., and will be obtainable through any bookseller. It can also be purchased at the offices of the British Medical Association, 429, Strand, London, W.C.2, or will be supplied by the Financial Secretary by post (10s. 9d.). Copies will be available at Stand No. 64 in the Exhibition of the British Medical Association which will be held during the Annual Meeting at Portsmouth.

#### EDUCATION OF THE PUBLIC AS TO CANCER.

THE annual general meeting of the Royal Society of Medicine was held at the Society's house on Thursday, July 5th, at 5 p.m. The report of the Council was passed without discussion, and the officers and Council nominated for next session were duly elected. Subsequently a special general meeting of the Fellows was held, under the chairmanship of the President, Sir William Hale-White, for the purpose of receiving and considering a report by the Council on propaganda for the prevention of cancer. At an ordinary meeting of the Society held on March 13th, 1923, and reported in our issue of March 24th, resolutions were adopted affirming that the public should be given more information as to the early signs of cancer and prospects of cure by means of treatment, and inviting the British Red Cross Society to conduct a publicity campaign by means of lectures and pamphlets. The Council of the Royal Society of Medicine appointed a committee to consider the matter and to prepare information which might be supplied to the British Red Cross Society to disseminate widely for the education of the public. This committee held several meetings, including two with a committee nominated by the Ministry of Health to consider the question of cancer. Sir Arthur Stanley attended one of the meetings, and offered the help of the British Red Cross in distributing knowledge to the public if the Royal Society of Medicine would supply the information, to be used by lecturers already provided by the Red Cross Society or embodied in leaflets. The committee felt unable to advise that information should be provided for lecturers, because the Royal Society of Medicine would have no control over what the lecturers might say. But having read the leaflets already distributed by some medical officers of health, the committee drew up a leaflet entitled "What ought to be known about cancer," and advised that the Royal Society of Medicine should supply it to the British Red Cross Society. The Council approved this report and submitted it to the special meeting. At first there seemed to be some doubt in the minds of the Fellows present whether the Society was already committed to the issue of a leaflet by the resolutions of the ordinary meeting on March 13th. This doubt was cleared away by Dr. A. M. H. Gray, one of

the honorary secretaries of the society, who stated that these resolutions were merely recommendations which could be accepted or rejected as the meeting wished. Sir Henry Morris expressed grave doubts as to the wisdom of joining with the Red Cross Society in a publicity campaign, though he was quite willing to consider the advisability of a pronouncement of its own by the Royal Society of Medicine. He felt also that some of the statements in the leaflet might produce anxiety in the minds of many people without any real advantage. Dr. W. S. A. Griffith objected to a statement about uterine haemorrhage after the menopause as too sweeping; and Sir StClair Thomson and others complained of omissions in the leaflet. One or two speakers expressed the opinion that propaganda on the subject would be better left to the medical officers of health. Owing to these and other criticisms a proposal to postpone the matter until the autumn session was eventually accepted without a dissentient. The Central Midwives Board has two excellent leaflets, one on cancer of the breast, the other on cancer of the womb, both drawn up by its chairman, Sir Francis Champneys. They are written in general terms, and in plain language convey information of first importance to all women. As is noted above, some medical officers of health have issued leaflets for local distribution. It is true that surgeons often find that the disease is beyond the reach of surgical help when the patient first applies for treatment and are naturally desirous that possible future sufferers should be instructed in the recognition and the early manifestation of the disease, but the Royal Society of Medicine is probably wise in giving this matter of a publicity campaign on cancer further consideration, for any leaflet issued under its authority should be very carefully worded so as not to appear to promise too much.

#### COMPARATIVE MEDICINE.

A SECTION of Comparative Medicine has been established by the Royal Society of Medicine, and was formally constituted at a meeting on July 6th, when Sir Clifford Allbutt was elected president. The section is open to duly qualified veterinary surgeons as well as to medical practitioners. Half the members of the council represent human medicine and half veterinary medicine. The vice-presidents are Major-General Sir Layton Blenkinsop, K.C.B., Colonel Commandant Royal Army Veterinary Corps, Lieut.-Colonel J. W. Brittlebank, C.M.G., R.A.V.C., Sir William Hale-White, President of the Royal Society of Medicine, Mr. Frederick Hobday, C.M.G., F.R.C.V.S., Major-General Sir William Leishman, K.C.M.G., F.R.C.P., F.R.S., Major-General Sir John Moore, K.C.M.G., F.R.C.V.S., Sir Leonard Rogers, M.D., F.R.S., and Mr. G. H. Wooldridge, F.R.C.V.S. The section will hold its first meeting at the beginning of next session, and thereafter will meet at 5.30 on the fourth Wednesday in each month. Mr. Hobday, who, it will be remembered, opened the discussion on animal pathology in relation to human diseases at the annual meeting of the British Medical Association last year, and who is this year a vice-president of the Section of Pathology and Bacteriology, has rendered important services in the formation of the section, and may without exaggeration be called its founder; if this be so then Sir Clifford Allbutt may be called its father, for it is to his persistent advocacy during many years and in several addresses to the British Medical Association that the recent impetus to the study of comparative pathology and medicine has been in the main due. Another evidence of the success of his labours is seen in the institution of the professorship of animal pathology in Cambridge, which will form part of the great school of comparative medicine and pathology that is growing up in Cambridge.

LONDON.

DIPHTEHERIA RESEARCH AT GHENT.

laboratories of which Dr. M. Henssler is director, particularly with reference to vaccination against diphtheria by means of toxin-antitoxin mixture, and the value of the Schick test. In 1921 Henssler and Clever<sup>2</sup> demonstrated that the inoculation of guinea-pigs with an appropriate mixture of diphtheria toxin and antitoxin conferred on these animals a high degree of immunity, manifested by the production of a large quantity of antitoxin, enabling them to resist many times the lethal dose of toxin and to survive a heavy inoculation of virulent diphtheria bacilli on the buccal mucous membrane. They showed also that the inoculation of human beings with a similar mixture of toxin and antitoxin determined a similar immunity, even in individuals positive to the Schick test and not possessing any appreciable quantity of antitoxin. They suggested that this method might be employed for the prevention of diphtheria, provided a carefully prepared product were employed. Working at this institute Dr. Verneuve studied the relation of the Schick reaction to cases of nasal diphtheria,<sup>3</sup> and observed that patients suffering from diphtherial ulcerative rhinitis generally gave a positive reaction to the Schick test; but vaccination with toxin-antitoxin mixture modified their receptivity and rendered them negative; he suggested that it might even be possible to prevent the diphtheria bacilli from living on the mucous membrane by suitable vaccination. To achieve this, however, it would be necessary to raise the circulating antitoxin to a high level. The development of a diphtherial toxin depends not only on the presence of the organisms and the receptivity of the host, but also on the existence

**PSEUDARTHROSIS.**

The complicated arrangement of the tissues found in pseudarthrosis and the transitional forms have been referred by some writers to a process of metaplasia—that is to say, the transitional forms have been held to indicate merely a regressive relationship between the various tissues. In a recent paper on the microscopic structure of pseudarthrosis Mitterhiller, following Roux, seems disposed to adopt the view, which is largely borne out by the observations described in his paper, that the differentiation of the tissues found in false joints is due to the varying mechanical forces to which the joints are subjected in different parts of their structure. Thus, where lateral or gliding movements of one portion of tissue on another are predominant, a fusure is produced; where such movements are associated with pressure, cartilage is developed; in situations where movement is at its minimum bone is formed, and fibrous tissue where the tissues are subjected to tension, as at the periphery of the bone-ends in angulation movements. The connective tissue, cartilage, bone, and joint capsule are held to arise from a single tissue or blastema, and similar relations are considered to hold in the regeneration of a joint as in its first development. Mitterhiller's observations were made on four cases of pseudarthrosis—two in the tibia of five and eleven months' duration respectively, one in the ulna of four years' duration, and one in the humerus of eleven and a half years' duration.

*Comptes rendus des Séances de la Soc. de Biol., March, 1923.*

Staffordshire General Hospital. He retired to Hastings in 1912, and devoted his energies to the work of the Society for the Propagation of the Gospel. He went on a world missionary tour in 1914, and also visited Peking with Mr. Rockefeller in 1919 for the opening of the Peking Medical College and Hospital.

## Medico-Legal.

### AN UNQUALIFIED PRACTITIONER.

At Woolwich Police Court on November 28th, before Mr. Waddy, Clarence Wilfred O'Donoghue, of Heavitree Road, Plumstead, was summoned for falsely using the title of "doctor" on October 13th, 21st, and 22nd, implying that he was registered under the Medical Act; alternatively he was summoned for pretending to be a general practitioner on the same dates. Mr. G. D. Roberts, instructed by Messrs. W. E. Hempson and Sons, solicitors, prosecuted on behalf of the Medical Defence Union. The case arose out of an inquest held by the Woolwich coroner on October 27th on a woman named Healy. The facts were sufficiently reported in the JOURNAL of November 3rd (p. 843).

At the police court Mrs. Walklin, niece of Mrs. Healy, gave evidence that when her son, aged 3 years, was ill, she, believing O'Donoghue to be a fully qualified doctor, called him in, and he examined the child and gave her a bottle of medicine, for which she paid 2s. 6d. Patrick Healy, son of the deceased woman, repeated the evidence he gave at the inquest as to the belief held by his mother and his family that O'Donoghue was a fully qualified doctor, and as to his attendance on his mother up to within an hour of her death.

The shorthand notes of the proceedings at the inquest were put in. These showed that O'Donoghue, in reply to the coroner, had admitted that he had no qualification registrable in this country.

The magistrate said that the Medical Defence Union had quite rightly taken up the case, and it was his duty to convict. The defendant would be fined the maximum penalty of £20 on the first summons and must pay 10 guineas costs, with the alternative of a month's imprisonment.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

At a congregation held on December 8th the following medical degrees were conferred:

M.D.—E. W. Todd.  
M.B., B.Ch.—L. S. Fry, C. Sturton, G. E. Burton, C. V. Patrick  
B.Ch.—J. M. Bickerton.

### UNIVERSITY OF LONDON.

It has been decided to institute a readership in pharmacology at the London School of Medicine for Women.

Dr. Lydia Henry has, on the nomination of the Board of Principal Teachers of King's College for Women, been appointed a member of the King's College Delegacy for the period ending February 24th, 1924, in succession to Dr. J. Lane-Claypon, resigned.

Professor A. E. Boycott, F.R.S., has been reappointed Director of the Graham Medical Research Laboratory for a period of one year as from January 1st, 1924.

Internal and external students who under the old regulations have followed an approved course which has included pharmacy and materia medica for the second examination for medical degrees, Part II, will not in future be required to follow courses in the same subject in preparation for the third examination for medical degrees.

Sir Wilnot Herringham has been elected chairman of the Gresham Legacy Committee for 1923-24.

### ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW.

The following have after examination been admitted as Fellows: Joseph Dunbar, James Hendry, John Marshall, Thomas D. Miller, John R. B. Robb, Sidney H. Waddy.

### ROYAL COLLEGE OF PHYSICIANS OF IRELAND.

At the monthly business meeting of the President and Fellows, held on December 7th, the following candidates, who had been successful at the Conjoint and Final Examination in November, were duly admitted to the licences in medicine and midwifery of the College:

F. J. N. Carney, A. E. Clements, M. H. Dobbyn, F. D. Fitzpatrick, W. G. C. Fitzpatrick, H. I. Hawkes, Rosaleen H. Hoskin, Kathleen O. M. Kennedy, Catherine M. King, G. A. Little, J. J. Marlborough, Sarah Matson, F. McConnoll, E. A. M'Nau, J. J. O'Donnell, J. O'Donnell, W. O'Neill, V. J. O'Toole, H. C. Patterson, G. F. Plant, P. B. Ryan, J. Unsworth, S. P. Wallace.

## Medical News.

THE Purvis Oration before the West Kent Medical-Chirurgical Society will be delivered to-day (Friday, December 14th), at 8.45 p.m., at the Miller General Hospital, Greenwich. The orator is Sir Thomas Horder; his subject is "Carcinomatosis."

A LECTURE on a tuberculosis settlement, illustrated by the cinematograph, is being given by Sir James K. Fowler at the Middlesex Hospital Medical School this day (Friday, December 14th) at 3 p.m.

THE Kensington Division of the British Medical Association has arranged a ball in aid of the Royal Medical Benevolent Fund. The ball will be held at the Kensington Town Hall on Tuesday, February 5th, 1924, from 9 to 2 o'clock, under the patronage of H.R.H. Princess Louise, Duchess of Argyll. Tickets, price 1 guinea each, or six for 5 guineas, can be obtained from the Honorary Secretary, Dr. Howard Stratford, 20, Upper Phillimore Place, Kensington.

THE house and library of the Royal Society of Medicine will be closed from Monday, December 24th, to Thursday, December 27th, both days inclusive.

THE Liverpool Psychological Society has been inaugurated under the presidency of Professor Alexander Mair, M.A., of the University of Liverpool, supported by Dr. Betts Taplin as vice-president and an influential committee. The society intends to pursue the systematic investigation of the recent developments of the science. Further information can be obtained from the Secretary of the Society, The University, Liverpool.

DR. W. L. P. BEVAN, formerly medical officer of health for Alton, has been presented by the townspeople with a fur coat, leather travelling bag, and an illuminated address on the occasion of his retirement from practice after thirty-five years' residence in the town.

THE next meeting of the Central Rhineland Surgical Association will be held at Frankfurt on January 12th, 1924, when the following subjects will be discussed: (1) Diagnosis of diseases of the female breast. (2) Results of operative treatment for spinal cord disease in spondylitis and fractures of the vertebrae.

THE Nobel prizes for 1922 and 1923 were formally presented in Stockholm on December 10th by the King of Sweden. Among those who attended the ceremony was Dr. A. V. Hill, Jodrell Professor of Physiology in University College, London.

It is announced by the Paris correspondent of the *Morning Post* that an international committee has been founded to establish an Institut Coué d'Education physique (Méthode par l'imagination). The committee includes several members of the medical profession in France.

PROFESSOR KARL SUDHOFF, the well known medical historian of Leipzig, has recently celebrated his 70th birthday.

DR. GEORGES GUILLAIN has been nominated professor of nervous diseases in the Paris Faculty of Medicine, in succession to Professor Pierre Marie, and Dr. Sicard has succeeded the late Professor Rénou in the chair of medical pathology.

MESSRS. J. AND A. CHURCHILL announce for early publication the fifth edition of Dr. Henry Jellett's *Short Practice of Gynaecology*, with 10 coloured plates and 318 illustrations in the text.

THE Secretary of the Nurses' Co-operation, 22, Langham Street, W.1, informs us that the year's work of the Nurses' Needlework Guild was displayed at the Howard de Walden Nurses' Club last week. The garments are distributed to various hospitals.

THE first number of a new quarterly Polish publication, which will publish articles on medicine, has been received, and is to be welcomed as a valuable addition to medical literature. Under the editorship of Professor A. Gluzinski, of the University of Warsaw, and with the official approval of the Minister for Art and Public Education, it will contain articles by members of the hospital staffs, and include accounts of the progress of medical research. An abstract in French is given of each article. The present number includes papers on the diagnosis of pulmonary syphilis, by Professor Gluzinski; on methods of determining hepatic insufficiency, by Dr. W. Filinski and Dr. W. Proszowski; on neutral fats in the blood, by Dr. Z. Gorecki; on cholesterol in the blood, by Professor W. Orłowski of Cracow University; on the sedimentation of red blood corpuscles, by Dr. Elconora Reicher; on von Pirquet's reaction, by Dr. L. Sobieszowski and Dr. Z. Michalski; and on the influence of pilocarpine upon the amount of sugar in the blood and urine, by Dr. J. Wegierko.

notably, or both. In compensation cases I have seen many instances in which the condition has been produced or made much worse either by supposed or real inattention to the person at the time of injury; or later on by someone depriving the amount of the injury received or by offering a quite inadequate sum as compensation.

The signs and symptoms in hysteria are as numerous and varied as the imaginations of the patient; and may be manifested in acute attacks lasting an hour or some days and coming on periodically, or may be more chronic and last months or years.

Alterations of sensation may lead to complaints of localized pains, sometimes in the head or spine, either the whole spine or a localized area, in the breast, over the heart, and frequently in the abdomen. Hypersaesthesia is more common than the spontaneous pain just mentioned, and these tender zones may be on the top of the head, above or below the breast, at the iliac fossae or the vertebral spines, and pressures are such as may start an acute hysterical seizure. More frequently loss of sensation is found, variously distributed, in one limb or part of a limb or both legs, but hemianesthesia is more common; as a rule the areas said to be affected do not conform to the anatomical distribution of the sensory nerve roots. In a limb, for instance, the limit of anaesthesia is generally a horizontal line drawn round the limb either just above or below a joint. Affections of vision are common, either total blindness of one or both eyes, marked contraction of the fields of vision, abnormal alterations of field of colour vision (instead of the normal white, blue, red, green, it may be red, blue, green), or colours may not be recognized or may be called by wrong names. I have never seen a bilateral homonymous hemianopia in hysteria; it is a manifestation very unlikely to be known to a hysterical subject. There may be unilateral or bilateral deafness, loss of smell or taste; speech may be affected either as aphonia or mutism or be manifested by mere gibberish.

The motor manifestations may be general or partial convulsions, local contractions, various forms of tremor, paralysis of various types, paraplegia, hemiplegia, or monoplegia. But close observation will reveal that in no case do they perfectly conform to the signs of similar affections due to organic disease; the "fit" is never a perfect epileptic attack, the spastic paralysis is never accompanied by the proper associated increased reflexes, nor the flaccid paralysis by wasting of muscles.

To put it shortly, the change, if any such exists, which produces such sensory or motor disturbances is not in any part of the brain or cord known to be directly connected with sensory or motor centres or tracts, but is a dynamic change in the highest cerebral cortex, a psychological change. Various manifestations may affect the digestive system—anoexia, starvation, ravenous hunger, vomiting, flatulency from air-swallowing, meteorism (and pseudocystitis), colic, constipation. Other visceral affections may be constant by cough, altered breathing, bringing up blood either by coughing or vomiting (such blood having been sucked from the gums or throat or injured tongue). About 1889, when resident in hospital, I was told that there was a girl in the surgical wards who was suffering from total loss of sensation of the left arm, and to report of the brachial plexus from a fall against a post in church. At the most earnest solicitations of her friends and herself, as the paralyzed arm was a constant hindrance to her, it was arranged to amputate the arm at the shoulder-joint. The night before the operation I was asked to see her as she had vomited a pint of blood. She was transferred to the medical wards. The next morning, from the peculiar transparency of a thin film of the blood, I surmised it was being sucked from the gums, and on examination found this to be the case. Needless to say no operation was performed and she was discharged cured. Polyuria, dysuria, ischuria, and vaginismus are also seen.

I believe that many of the so-called trophic and vasomotor changes described in hysteria are not changes due to diseases but are artificially produced. I refer to the bloody stagnata, the blisters, the gangrenes, the erythematæ, and the vaginismus are also seen.

Nevertheless to say no operation was performed and she was discharged cured. Polyuria, dysuria, ischuria, and vaginismus are also seen.

Nevertheless to say no operation was performed and she was discharged cured. Polyuria, dysuria, ischuria, and vaginismus are also seen.

Although hysterical subjects may possibly sometimes suffer from a self-induced hypnosis or may apparently have no recollection of what has occurred during an acute attack, or may have a simulation of loss of memory of the whole life-history previous to a particular attack, these, to my mind, are no more real than a hysterical flaccid motor paralysis. It is most important also to remember that however unconscious a hysterical person appears to be, it is probably always a simulated unconsciousness; at any rate that is my personal experience. Indeed, I go further and maintain that, however unconscious hysterical subjects may appear to be, they are really intensely "wide awake" and are watching them. A psychic condition of the utmost importance in hysteria is hypersuggestibility; so marked a feature is it that Babinski has suggested the name "pitiatism" (*pitie*, I persuaded) for hysteria. I thoroughly agree with him that many of the manifestations seen, such as hemianesthesia and various types of paralysis, have unconscious suggestions been suggested to the patient by the medical examination, and the more they appear to be the real thing the more they have been suggested.

It would take too long to consider the differential diagnosis of each hysterical manifestation; and indeed it is not necessary to do so. All that has to be remembered is that the hysterical simulation is never perfect and never fully conforms to the anatomy and physiology of the nervous system.

Treatment also must be dismissed in a few words. In very acute cases, such as a "fit," a sudden shock, such as a strong faradic current applied to the neck or a douche of cold water on the head, may cure at once.

A boy, aged 18, was brought into hospital one night in great haste, said to be suffering from hydrophobia; he was in convulsions, and there was a vague history of a dog bite some weeks before. As I was the only man in hospital who had ever seen genuine hydrophobia, I was called up to see the patient. The convulsions were of the irregularly bizzare hysterical type, and when I approached the boy he "backed" at me and tried to bite me. A strong faradic current applied suddenly to his neck promptly cured him.

But in chronic cases any such violent methods do the greatest harm; isolation from friends and relations is almost essential, and the doctor and nurse must sympathize with the patient, and go fully into the life-history to discover the reason why the morbid craving has arisen. In this way the patient comes to the conclusion that at last there is someone who understands her, and when once such confidence has been gained the medical man can without difficulty persuade the patient to a normal condition. Of course, the sympathetic attitude must be of the pervasive, encouraging, optimistic type, and not the coddling and pessimistic type which makes things worse.

Neurasthenia may be defined as a disease of the nervous system without known pathological changes in which there is a persistent weakness and irritability of nerve centres due to chronic overwork of neurones and manifested by purely subjective symptoms—that is, by altered feelings.

In health, fatigue is followed by a repose during which the cell is restored, and in animals the swelling of the cell body and fatigue have been observed—the swelling of the cell body and dissolution of part of the chromophil substance, followed during repose by restoration in size and of the chromophil particles. But if fatigue is either too severe or too prolonged such restorative changes may not occur and the altered cells become at first more irritable and more susceptible to fresh fatigue, and finally their function is lowered. There is no common standard of fatigue for all men, a point beyond which fatigue must not go if an ordinary repose is to restore the used cell to the normal. But a sharp line must be drawn between the person with a neurotic heredity and the normal.

THE sixteenth annual report of the British Guiana Society for the Prevention and Treatment of Tuberculosis contains records of the work of three dispensaries in Demerara and one in New Amsterdam. Six lady health visitors are associated with these; 8,844 domiciliary visits were made in the course of the year, and milk, disinfectants, and respirators were distributed. The committee urges that all this special tuberculosis work ought to be made part of the medical service of the colony and be under a whole-time tuberculosis officer. So far it has not been possible to undertake the routine inspection of school children. There is in the report a note by Dr. Massiah on treatment by a preparation of gazelle in honey, which he considers a successful palliative but by no means curative. Treatment was unsatisfactory to a large extent because patients ceased to attend when they began to improve, and so the maximum benefit was not obtained. It has been found very difficult to isolate advanced cases owing partly to lack of hospital accommodation and the absence of any scheme of compulsory segregation.

MR. PHILIP KRUSEMAN, publisher (The Hague, Noordeinde 91), has again issued a medical art calendar of the same general character as those that have appeared in previous years—that is to say, it contains reproductions of a number of paintings and engravings representing scenes of more or less medical interest, ranging from the travelling charlatans and dentists to operations and lectures on anatomy. This issue is dedicated to the Netherlands Association for the Advancement of Medicine, which was founded seventy-five years ago. The price is 6s., post free.

IN the notice of the *Medical Directory* for 1924, published last week, it was said that the list of practitioners beyond the seas "does not include those who hold degrees from Dominion Universities but have not taken diplomas or degrees in the home countries." The statement ought to have been "but have not registered in the home countries." So far as we are aware no directory of Dominion practitioners who have not registered on the *British Medical Register* is available.

IN a pamphlet consisting of articles reprinted from the *Hamilton Advertiser*, Dr. Maxwell Adams—the fourth of the name—continues his story (mentioned in the *BRITISH MEDICAL JOURNAL* of April 23rd, 1923) of the medical family to which he belongs. The matter now published is taken mostly from an autobiography left by Dr. Maxwell Adams *primus*; it tells how this "dynasty of doctors" began, how he, through many hardships, and whilst a married man with wife and family to maintain, succeeded in completing his medical curriculum in Edinburgh in the early years of last century, and entered on practice there.

THE jubilee of the Boston University medical school has recently been celebrated. In one sense the school is older than this, since seventy-five years ago Dr. Samuel Gregory opened the New England Female Medical College in that city, which, on the death of its founder, was taken over by the university and opened as its medical school.

THE Tropical Diseases Library, now arranged in the building of the London School of Tropical Medicine (23, Endsleigh Gardens, N.W.1), was formed by the amalgamation of the libraries of the School and of the Tropical Diseases Bureau. The annual report of the librarian, Mr. Cecil C. Barnard, B.A., shows that the joint library continues to increase and that great efforts are made to keep it up to date. Recent additions include the most important new publications on tropical medicine and a large collection of older German volumes particularly rich in books on cholera. Space had been found in the reading room for an increased number of monographs, so that the number of volumes immediately accessible to readers has increased from 250 to 715. A list of a few numbers of periodicals and reports missing from sets can be obtained from the librarian, who will also be prepared to discuss the disposal of duplicate numbers of certain journals with librarians of other institutions. Volumes can be borrowed, and the library also has a subscription with Lewis's Lending Library. A card catalogue, containing authors and subjects in one alphabetical sequence, is in course of preparation.

AN intensive course at the North-East London Post-Graduate College, Prince of Wales's General Hospital, will begin on February 4th, 1924, and will last for fourteen days. It will include lectures and demonstrations of clinical methods and cases, and work in the general wards and special departments of the hospital. Those proposing to take the course should notify the Dean not later than January 31st.

PROFESSOR R. KRAUS, Director of the Serum Institute at Sao Paulo, has resigned his appointment and returned to Vienna.

THE next Congress of the Royal Sanitary Institute will be held at Liverpool from July 14th to 19th, 1924, by invitation of the Lord Mayor and City Council.

## Letters, Notes, and Answers.

*As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.*

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the *BRITISH MEDICAL JOURNAL* alone unless the contrary be stated.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the *BRITISH MEDICAL JOURNAL* are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

THE postal address of the *BRITISH MEDICAL ASSOCIATION* and *BRITISH MEDICAL JOURNAL* is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the *BRITISH MEDICAL JOURNAL*, *Atiology Westrand, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY and BUSINESS MANAGER (Advertisements, etc.), *Articulate Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera Westrand, London*; telephone, 2630, Gerrard. The address of the Irish Office of the *British Medical Association* is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4751, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

## QUERIES AND ANSWERS.

WE are asked what can be done to prevent players on a certain football ground in the tropics from suffering septic infection from slight scratches that they may receive. The ground is liable to contamination by human and cattle excreta, but the former at least can be prevented or checked. A football ground ought, of course, to be well scavenged, but even so, we conceive that any attempt to disinfect the soil must fail. In this country we believe that it is now customary to treat scratches or small wounds received at football with tincture of iodine—that is to say, to treat the patient and not the ground.

### INCOME TAX.

#### *Legal Expenses.*

"B. S. F." inquires whether the legal charges in connexion with a partnership deed, necessitated by the introduction of a new partner, are an allowable expense for income tax purposes.

\*. Such expenses are not incurred in the carrying on of the profession, but in connexion with the creation of the firm; they are analogous to the formation expenses of a company, are of a capital nature, and not allowable.

#### *Succession to a Practice.*

"L." bought a practice in January, 1922, and paid income tax on the basis of his predecessor's assessment for the period to April, 1922. He was asked to send in an estimate of profits for the year to April, 1923; did so, and paid tax thereon. For 1923-24, however, he has been assessed on the basis of the previous three years' average profits of the practice.

\*. The last-mentioned basis is correct where there has been a definite succession in a practice. The request for 1922-23 and resulting assessment were apparently based on a misapprehension of the facts by the authorities.

## LETTERS, NOTES, ETC.

### CIRCULATION AND ASSIMILATION IN PLANTS.

SIR JAGADIS CHUNDER BOSE, F.R.S., of Calcutta, addressed the Royal Society of Medicine on December 6th on some further work he has done on circulation and assimilation in plants. Strasburger's statement that poisoning did not affect the ascent of sap, and that therefore the movement of sap could not be due to the physiological action of living cells, had been widely accepted, but his own observations with a special apparatus showed that complete arrest of sap did take place under the action of poison; he concluded, therefore, that the movement of sap in living plants was essentially due to cellular activity. An active tissue exchange took place throughout the length of the tree, and the propulsion of sap was due to cellular pulsations in regular sequence. Striking results were produced on these pulsations by the action of anaesthetics; a small dose of ether, for example—acted as a stimulant and increased the rate of ascent of sap. This cellular activity underwent periodic variation in response to environmental changes during twenty-four hours. The pulsatory movement of a plant cell was ultra-microscopic, but by experiments with an electric probe in circuit with a recording galvanometer, the probe being gradually introduced

across the plant so that its tip came into contact with successive layers of cells, he was led to conclude that intense and ceaseless pulsations were taking place behind the placid exterior. It was through these incessant internal activities that the tree was enabled to raise large quantities of water to a height which, in the giant eucalyptus, reached 450 feet. The energy for doing this work was obtained by the breakdown of complex chemical substances in internal combustion or respiration, and he had devised what he called a photosynthetic recorder to register certain of these changes. This instrument, he said, was sensitive enough to measure a photosynthetic deposit of carbohydrate as minute as one-millionth of a gram. It was a device whereby the evolution of oxygen—a very sensitive indicator of photosynthesis—was recorded electrically by successive dots on a revolving drum. It was found that minute traces of various chemical agents would induce an extraordinary enhancement of assimilation in plants. Extract of thyroid gland, in the dilution of one part in a billion (that is, French measure, equal to 1,000 million), produced a maximum increase of activity of about 70 per cent. The effect of doses of iodine was more or less similar. The demonstration of the effect of minute traces of chemicals on assimilation of plants was of special interest since it offered some analogy to the effects of ultrameasurable quantities of vitamins on general assimilation and of hormones on physiological reaction. The plant was a multicellular organ, and hence the necessity arose for intercommunication and interaction between more or less distant organs. This was accomplished in two different ways, the first being exemplified by hydraulic convection of liquids carrying chemical substances in solution, and the second by the conduction of excitatory change along certain tissues in the plant which functioned as nerves. The plant and the animal were similar in their contractile movement under stimulation, their reaction to particular drugs, their cell-to-cell propagation of pulsatory movement, their circulation of fluid by pumping action, their nervous mechanism for the transmission of excitation, and their reflex movements at the distant effector. He concluded that the simpler type of plant organism offered scope for investigation the pursuit of which would no doubt lead to the solution of many perplexing problems of animal life.

#### SPIRIT IN HAIR WASHES.

SEVERAL correspondents have written to us with regard to the note on this subject published in the JOURNAL of December 1st (p. 1072), and we find that the information in the *Extra Pharmacopoeia* was incomplete. The Revenue Act, 1906, clause 13, laid it down that a retailer must not use methylated spirit in any art or manufacture unless he has been authorized to do so; but subsequently the Board of Customs and Excise issued an Order (1913) stating that "mineralized methylated spirit may be used by registered chemists and druggists in the preparation of lotions for external use, when prescribed by duly certified medical practitioners." Chemists, however, are liable to a penalty if the methylated spirit is used in any preparation capable of being consumed as a beverage or used internally as a medicine.

#### ANTE-PARTUM HAEMORRHAGE AND ECLAMPSIA.

DR. J. LEWIS THOMAS (Newport, Mon.) writes: May I recall briefly a somewhat exciting experience of a winter's day in 1910. A butcher's wife asked me to see her as I was going home to lunch. She complained of a "dreadful headache" with much giddiness, and said that she was passing very little urine. As she was more than eight months pregnant the situation was not pleasant. The urine was practically solid on boiling. She was ordered to bed and the usual treatment advised; she was specially requested to send for me at the slightest signs of labour or convulsions. About 9 p.m. I was sent for, and on arrival found that she had got on the bed in ordinary attire. She was unconscious and actively and almost continuously convulsed. I applied a chloroform mask, well saturated, over her face. While a nurse was being secured I examined for signs of labour and was delighted to find placenta praevia. The os was fairly patulous and soft; and as the bleeding was very free I performed podalic version without removing the hand. The convulsions ceased after delivery and consciousness soon returned. The baby seemed recently dead. The same woman had given me great anxiety four years previously owing to post-partum haemorrhage.

#### ACCIDENTAL HYDROTHERAPY.

DR. J. N. LORING (London) writes: The following incident may appeal to those interested in hydrotherapy. Last year I was acting as surgeon to a ship on the Australian coast. We were lying at anchor in the Spencer Gulf, fifteen miles from Port Pirie, when one of the men was taken ill. His temperature rose to 103°, and there was violent purging accompanied by cramp-like abdominal pains. He was restless and slightly delirious during the night, and it was decided to remove him to hospital before proceeding on our voyage. Accordingly a small open motor boat arrived, and the patient, whose temperature was now 103.5°, was laid on the bottom of the boat. The run to Port Pirie occupied about an hour and a half. The patient vomited three or four times and passed numerous motions, but his pulse remained good throughout the journey. A tablespoonful of brandy was given every twenty minutes. During the passage the patient was drenched repeatedly with salt spray. The launch shipped a few gallons of water, so that the blankets which covered him became nearly saturated. On entering hospital ashore his temperature was found to be 101°, and he fell into a quiet sleep. He woke about three hours later and said he

felt much better. His temperature had risen to only 101.5° and was never again higher than this. Henceforward, I am informed, his progress was uninterrupted. This somewhat unconventional method of administering hydrotherapy seems to have lowered the temperature effectively without producing any harmful results.

#### ETHYL CHLORIDE-CHLOROFORM SEQUENCE.

DR. THEODORE M. KENDALL (Newport, Isle of Wight) writes: I have been much interested in a controversy which has been occupying the pages of the JOURNAL. I notice that many well known men who ought to be able to speak with authority have been condemning the use of chloroform as a general anaesthetic, and have been pointing out the dangers of such use. I have been a busy man for many years and have practised in country places where other help could not be obtained. I have never found chloroform fail me, nor have I—very fortunately, of course—ever experienced any of the dangers alleged to attend its use. I have found chloroform a safe and valuable assistant in cases of childbirth and for operations in young children. I have frequently administered it, in the half-reclined position of the dentist's chair, and have never been confronted with any mishap. I cannot understand why it is considered now so dangerous or why there is a tendency to push its use aside in favour of other anaesthetics which to my mind do not produce such a comfortable and safe anaesthesia. Maybe I have been fortunate in my patients, but still I have been at times fifty miles from any town and have had to administer the anaesthetic and perform the operation quite unaided in order to save life.

#### THE CAUSE OF HERNIA.

DR. MARTIN J. CHEVERS (Withington, Manchester) sends us a communication commenting on certain statements in the brief note (November 10th, p. 883) giving a summary of Sir Arthur Keith's Banks Memorial Lecture on the incidence and cause of hernia. Dr. Chevers states that after over a quarter of a century's observation in general practice he has come to the firm conclusion that hernia, whether in infancy, adolescence, or old age, is due to a weakness of the guarding tissues, whether muscular or connective, which weakness is brought about solely by rheumatism, oftener than not of the incipient form; he attributes the smaller incidence in the female to the exceptional strength of this neighbourhood in their case; but as a set-off they have vaginal prolapses with, in his opinion, a similar etiology.

#### SEPTIC PNEUMONIA WITH HAEMORRHAGIC COMPLICATIONS IN AN INFANT.

DR. WALTER FISHER (Kalene Hill, N. Rhodesia) sends the following note which he recently received from a missionary living many miles from medical help: "For the first seven days (after birth) all went well with mother and child (the child 7 lb. in weight and apparently healthy). On the seventh night the child had poor appetite, and next morning some signs of colic, very small curd being noticeable in stools. . . and a few hours later the whole leg became bluish and white in patches. . . The breathing became heavy, like that of bronchopneumonia. . . The temperature rose to 105°-107° F. . . his stools turned tarry black, and later the white and blue patches spread. On the tenth day the temperature came down, but the child took no nourishment and died in the evening, a large amount of brown mucus coming out of nose and mouth immediately after death."

\* \* In attempting to reach a diagnosis from the data supplied it may be assumed that all the striking morbid conditions have been reported—for example, that there was little or no vomiting, and that the changes in the leg were chiefly discoloration of the skin without gross swelling. The height of the fever, together with the laboured breathing, make it almost certain that acute pneumonia occurred on the seventh day, and killed the child three days later. But the other clinical facts, the bleeding from the bowels and the condition of the leg, suggest that the pneumonia was not the more common pneumococcal type, but septic and probably streptococcal. The most likely source of septic infection at this time is the umbilical cord; and even if there were no apparent inflammation at the navel it is quite possible that there was a hidden focus in the cord tract, from which a haemolytic streptococcus set up septicaemia, septic pneumonia, with haemorrhages from the intestinal mucosa. The condition of the leg seems more difficult to explain. But cases of umbilical sepsis and septicaemia have been reported where a spreading cellulitis has reached the groin along the preperitoneal tissues, and has caused there abscess or septic thrombosis. In the present case it would not be possible to do more than guess at the condition of the leg, in the absence of a fuller report, and to suggest that it was some circulatory disturbance produced by septic mischief in the groin.

#### VACANCIES.

NOTIFICATIONS of offices vacant in universities, medical colleges, and of vacant resident and other appointments at hospitals, will be found at pages 31, 32, 33, and 35 of our advertisement columns, and advertisements as to partnerships, assistantships, and locumtenencies at pages 34 and 35.

A short summary of vacant posts notified in the advertisement columns appears in the Supplement at page 276.

# SOME APPLICATIONS OF PHYSIOLOGY TO MEDICINE.

## III.—BLOOD PRESSURE AND HEART ACTION IN SLEEP AND DREAMS:

THEIR RELATION TO HYPERTENSION, ANGINA, AND SUDDEN DEATH.\*

J. A. MACWILLIAM, M.D., F.R.S.,

PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF ABERDEEN.

(From the Physiological Laboratory.)

THIS is an important, and in some of its aspects an almost unexplored, field of study, with an obvious bearing on many questions. Precise data on the subject are naturally somewhat difficult to obtain. The present paper contains some results of slowly accumulating observations carried on by the writer as opportunities presented themselves over a long series of years.

### Changes in Normal Sleep.

The slowing of the pulse rate (noted by Galen) and the respiration during sleep has long been known to be accompanied by a lowering of bodily temperature, a great reduction in metabolic activity and heat production, depression of reflexes, diminished secretion, etc. There is general agreement as to a definite lowering of the systolic blood pressure, varying in different conditions and as recorded by different observers, but often amounting to 15 to 30 mm. Hg at the end of two hours' sleep; the pressure gradually rises in the later portion of the night's sleep. Greater reductions have been noted in persons with high pressures in the daytime. Thus some years ago Brooks pressures in the range of 204 mm. found a fall of 44 mm. after two hours' sleep; at the moment of waking it rose 22 mm. from the level present in sleep. More recently, in the last year or two, C. Miller in normal persons found the systolic pressure to be down to 84 mm. in men and 88 mm. in women during sleep, after a small dose of veronal. Blum, in men and women with moderate day pressures, recorded falls of 15 mm. and 21 mm. respectively, while in those with high day pressures the falls averaged 31 mm. and 38 mm. Much importance has been attached by some writers to this reduction of pressure; it has even been regarded, though on very insufficient grounds, as the determining cause of sleep.

It must be borne in mind that in the recumbent position a fall of aortic pressure would be necessary to prevent the pressure in the cerebral arteries from being higher in the horizontal than in the erect position—from the influence of gravity, the hydrostatic factor of the weight of the column of blood between the level of the heart and the brain. Allowance for this factor in the recumbent posture cuts down the observed lowering of arterial pressure to a comparatively small amount, probably much too small to play the potent role that has been ascribed to it in the production of sleep. Further, the crude analogy of unconsciousness caused by an arrest or sudden great diminution in the blood supply to the brain cannot be regarded as valid when applied to the induction of the normal process of sleep.

Diminished vascularity of the brain substance during sleep has been described by various writers (Dunham and others) on the ground of direct observations on exposed portions of the brain surface. A similar change has been inferred from the plethysmographic records obtained by Mosso and his followers, who found evidence of an increased volume of blood in the limbs (arm, etc.) during sleep, and assumed this to be attended by lessened vascularity of the brain, the converse conditions being present after awakening. But this hypothesis has to be revised in view of Leonard. A communication on this subject was made to the International Physiological Congress at Edinburgh on July 25th, 1923. Part I of this series was published on January 13th, 1923 (p. 51), Part II on August 11th, 1923 (p. 219).

inseparable from it. In it the patient does not merely complain of altered sensations and feelings, but has gone a stage further and translated these into terms of definite disease, from which he is suffering, and his conduct is modified accordingly. Many patients have an idea that they may have syphilis or cancer, or ulcer of the stomach, and consult their doctor on this account. But this in itself does not constitute hypochondriasis, for after adequate examination and explanation they may be convinced that their fears are groundless. It is the person with the fixed idea, unalterable by argument, that he has some definite disease and will not therefore take food, or only certain foods, and will not touch other persons for fear of contaminating them, or will not walk lest he suddenly drops down dead from heart disease, or who spends his time constantly examining some part of his body which he considers diseased, or constantly washes and changes his linen because he thinks he is verminous—that is the true hypochondriac. It is in some cases a truly terrible affection, and is often as incurable as a case of chronic delusional insanity.

### Tramatic Neuroses.

It would take too long to discuss tramatic neuroses in all their aspects, complicated and increased as they have been by the Workmen's Compensation Act, but a few words are necessary. No signs or symptoms are found in those cases differing from those mentioned in my previous remarks. The manifestations may be those of malingerers, of hysteria, of neurasthenia, of hypochondriasis, or even of true melancholia. The only peculiarity is that after trauma it sometimes happens that there is a mixture of hysteria and neurasthenia with some malingerers. According to legal decisions hysteria and neurasthenia (including, of course, hypochondriasis and melancholia) are psychological or physical changes and have to be compensated. But malingerers, being pure fraud, gets no compensation, and the great difficulty is to prove that the case is one of pure malingerers. Sometimes the doctor can discover this himself, but at other times it can only be proved by outside evidence. For instance, a man after injury may have paraplegia, not organic, as it does not conform to this, but apparently hysterical. If, however, there is evidence that when not under observation so far as the man knows he is seen to walk and run in a perfectly normal manner he is an obvious fraud.

Psychical shock producing neurasthenia may occur without physical injury. A lady in a tramcar saw a following car approaching too rapidly and thought the guard would be killed, but beyond a very slight impact of the cars nothing happened. But the lady got out of the car in a state of fright, fainted, and was afterwards at home suffering from profound neurasthenia for weeks, and was given heavy damages at the assizes.

Again, a man is in very great danger owing to an alarming accident, say, of a falling crane crushing him to death; perhaps he escapes with a bruised foot which soon recovers, but he develops neurasthenia lasting many months. And it is not uncommon for some simple injury, say, of a finger, to be followed by hysterical paralysis of sensation and motion of the same arm. In these cases, although the original slight injury soon heals, compensation must be paid so long as the neurasthenia or hysteria persists. Finally, I would say that although after trauma the neurasthenia is due to a molecular change similar to those of an ordinary acquired neurasthenia from business worry which recovers perfectly in weeks or months, yet I think that in cases of more severe injury due to falls from heights or injuries to head, and also if the accident has been a very terrifying experience (such as being whirled round a revolving shaft), it is possible for the nervous molecular changes to be so intense that recovery never occurs, in spite of full compensation having been paid. The man is "never the same as he was," and occasionally passes into melancholia and sometimes commits suicide.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 424. Precancerous Dermatitis of Bowen.

L. SAVATARD (*Brit. Journ. of Derm. and Syph.*, November, 1923, p. 405) reports a case which clinically and histologically was identical with cases of precancerous dermatitis described by Bowen. It is that of a woman who presented herself with a chronic dermatitis in the region of the right hip-joint involving an area of 6 inches by 3 inches. White scar tissue occupied the centre, round which were numerous red papular lesions, discrete and confluent, some slightly and others more distinctly raised above the skin surface. They were covered by adherent scales and crusts, were firm without being indurated, and did not appear to infiltrate the true skin; when removed a raw oozing surface was left. The patient had no subjective symptoms. The condition had commenced as a red spot on the outer aspect of the thigh thirteen years previously; this gradually increased until, five years later, it formed a red plaque about the size of a half-crown. At this time it was removed, but recurred at the periphery of the scar tissue, and suggested clinically a superficial gummatous infiltration, the Wassermann test, however, being negative. With the idea of a possible tuberculous origin in his mind the author thoroughly scraped the lesion, which then healed soundly, but again recurred at the periphery of the scar. Histological examination revealed a typical picture of Paget's disease—marked acanthosis of the rete cells with dyskeratosis, the upper part of the corium infiltrated by plasma cells and small round lymphocytes, and dilatation of the blood vessels. Clinically the condition was not typical of an extramammary Paget's disease; there was no vivid red colour and no ulcerated bleeding surface. Clinically and histologically, however, the identity with two cases of precancerous dermatitis previously reported by Bowen seemed undoubted. The author is not in agreement with other observers, who would differentiate Paget's disease from the dermatitis of Bowen, and suggests that the hyperkeratosis of Bowen and the difference in the clinical picture may be attributed to the difference in the situation. He submits that the precancerous dermatitis of Bowen is the extramammary precancerous dermatitis of Paget. Reviewing reported cases, he claims that the dyskeratosis on which some observers have placed their cases in the category of Bowen's dermatitis is not infrequently met with in basal and squamous celled carcinomas, and that, moreover, omitting the vegetating hyperkeratotic type of lesion, marked hyperkeratosis is not a feature of Bowen's cases.

### 425. The Treatment of Bronchiectasis by Artificial Pneumothorax.

J. TILLMAN (*Acta Med. Scand.*, October 4th, 1923, p. 515) records his experiences of artificial pneumothorax in 5 cases of bronchiectasis, and brings this number up to 65 by collecting cases published by other authors. His survey of this combined material shows that the disease was unilateral in 61 per cent., and in another 20 per cent. it was not stated whether the disease was unilateral or bilateral. Only in 3 cases was bilateral collapse of the lungs attempted, in none with success. In about two-thirds of all the cases definite improvement was effected as far as immediate results were concerned. But of the ultimate results—for example, the results more than a year after the institution of treatment—little is yet known. On the whole the author considers this treatment beneficial, but it is not yet possible to say which cases of bronchiectasis will do well under this treatment and which will not. In one of the author's cases the treatment had lasted for six years, the results being excellent. Though there was still a little purulent sputum it had ceased to be malodorous, and the patient was able to live a fairly active life. In another of his cases the sputum disappeared altogether and the patient felt perfectly well, although the lung was not completely collapsed.

### 426. Renal Function in Diabetes.

E. URECH (*Ann. de Med.*, September, 1923, p. 231) states that although the disturbance of carbohydrate metabolism plays an important part in the course of diabetes, renal lesions are not uncommon, though they have hitherto received little attention. Histological examination of diabetic kidneys often shows serious changes, even though nephritis has not been recognizably clinically. Polyuria sometimes provokes functional hypertrophy. In some cases there is coagulation necrosis of the epithelium of the convoluted tubules, or even

glycogen infiltration of the epithelial cells, and some authors state that this may produce diabetic coma. It is therefore important to test the other renal functions in diabetes, in addition to estimating the quantity of sugar. Urech has estimated the excretion of urea, chlorides, and acetone, in addition to the measurement of the total excretion of urine and of sugar, and records his results in several diagrams and tables. He concludes that it is not the severity of the diabetes, the quantity of the blood sugar, nor the presence or absence of acetone which has the determining influence on the renal functions of diabetics, but the condition of their vessels (arterial or renal sclerosis), which causes disturbance of elimination. Three of the younger patients examined had severe diabetes, yet their renal functions were unimpaired. Among the older patients the disturbance of carbohydrate metabolism was sometimes slight, yet their renal functions were definitely impaired. This diabetic sclerosis does not affect uniformly the various organs, but it assumes certain distinctive characteristics which appear earlier and more definitely in the lower than in the upper limbs. This explains the persistence of ulcers, of gangrene, of cerebral haemorrhages, and of attacks of angina pectoris. Does diabetes predispose to sclerosis? Although Urech's investigations are not complete he thinks that further inquiry will show that sclerosis does not occur at an earlier age, nor is it more severe in diabetics than in other patients of equal age.

### 427. The Nervous Phenomena in Graves's Disease.

J. HOLST (*Acta Med. Scand.*, September 6th, 1923, p. 395) has investigated about 200 cases of Graves's disease, most of which were operated on in a hospital in Drammen. In none of the cases of definite Graves's disease did he fail to find nervous symptoms such as great restlessness, and he attempted to answer the question: Are the nervous symptoms the precursors of, or the sequels to, genuine Graves's disease? He inclines to the latter view, and he notes that in certain cases of insanity the Graves's disease had lasted a considerable time before any mental symptoms appeared. With regard to the popular view that psychic shock may give rise to Graves's disease, he has investigated the histories of 120 cases of primary Graves's disease, and only in 5 could he find an account of a shock, such as an abdominal operation, being regarded by the patient as the cause of the first symptoms of the disease. In these 5 cases there was a history of great sorrow in one case, of pregnancy in another, an abdominal operation in another, and infection in the remaining two cases. In all the other cases in which there was a history of a psychic trauma responsible for the Graves's disease, investigations showed that there had been definite signs of this disease previous to the shock, which may have led to the diagnosis of the disease, but could not have caused it. But though shock is not the common cause of Graves's disease which it is supposed to be, the course of this disease may undoubtedly be seriously influenced by psychic trauma.

### 428. Late Sequelae of Malaria.

LE DANTEC, M. LEGER, and HESNARD (*Gaz. Hebdom. des Sciences Méd. de Bordeaux*, October 7th, 1923, p. 487) read papers on this subject at the seventeenth French Congress of Medicine. Le Dantec observed that the existence of malarial arthritis described by Lancereaux and Potain had been confirmed by skiagrams which showed definite dilatation of the aorta during a malarial attack, which was relieved by quinine, but in chronic cases a definite arthritis accompanied by dilatation supervened. The peripheral arteries are not infrequently attacked by endarteritis obliterans, leading to dry gangrene, especially in the extremities, face, or genitals. In Le Dantec's cases blood tests were negative to syphilis and bacterial invasions, but the blood contained many parasites—*P. falciparum* or *P. vivax*. In women chronic malaria induces sterility, or, in patients who become pregnant, abortion occurs frequently. Surviving infants are cachectic, and the mortality among the newborn is 75 per cent. Le Dantec recommends intramuscular injections of basic quinine formate in glucose solution, in acute cases, but he relies upon quinine sulphate (in cachets) by the mouth, with a glassful of lemonade, in chronic cases. M. Leger states that splenomegaly is usually due to infection by *P. vivax*. He describes the effects of chronic malaria on the liver—the formation of bile and of urea is gravely deranged. Many cases of pneumonia in tropical countries are due to malaria, and the plasmodia may be found in the sputum. These cases are

Hill's work establishing the practical accuracy of the old Rousso-Kellie doctrine that the amount of blood within the skull is a constant quantity, whilst its distribution in arteries, capillaries, and veins respectively varies in different conditions. Weber's more recent work indicates that when there is less blood in the limbs there is more in the abdomen, not in the brain.

Pléthysmographic observations have clearly shown responsiveness to stimuli during sleep, inducing alterations in the volume of a limb and showing certain changes in the distribution of the blood in the vascular system. But such observations give no information as to the state of the aortic blood pressure, upon which the pressure in the cerebral arteries depends.

*Fluctuations of the Period of Sleep to Some Diseases*

In accordance with the accepted view that the vital activities, as indicated by heart action, respiration, blood pressure, temperature, and general metabolism, reach their maximum in the early hours of the morning, it is easily intelligible that death from illnesses involving progressive exhaustion and a gradual running down of the machinery of life should often take place in that period. Statistics are available which bear this out. Thus Schneider (Berlin), in a total of nearly 58,000 deaths, found that deaths were most common between 4 and 7 a.m. nearly 14,000 deaths, fixed the highest mortality between 5 and 6 a.m.

Many phenomena of disease, aggravation of morbid conditions and symptoms in the night, can be brought into relation with the general lowering of vital activities during sleep—for example, some respiratory troubles which may in some cases be associated with the depression in respiration naturally occurring in that period, the reduced sensitivity of the respiratory centre to the normal excitations by CO<sub>2</sub> with the consequent modification in the state of the blood, heightening of the grade of acidosis which may be present, development of Cheyne-Stokes respiration, etc., often associated with attacks of severe dyspnoea, and

*Sudden Death in the Night.*

In contrast with the associations of depressed functions during sleep as affecting some of the manifestations of disease there is another class of phenomena for which a different interpretation is required, for they obviously do not lend themselves to explanation by the lowered activities of nightly rest and sleep.

In connection with the subject of haemorrhages of various kinds and their times of occurrence and mechanism, questions arise. The time incidence of many vascular ruptures is naturally accounted for by the conditions prevailing at the moment of their occurrence—rise of blood pressure and increased stress on the walls of the vessels determining rupture at the weakest part—for example, muscular effort, the influence of gravity in certain postures, abdominal straining, etc.

But why should a weakened vessel give way during the period of nocturnal rest and sleep, since a lowered blood pressure is naturally protective against rupture? Why cerebral haemorrhage should frequently occur in the night is a question that was asked long ago by Sir Samuel Wilks and apparently never answered. In view of the lowering of blood pressure and a diminished blood flow through the brain in sleep, why should a cerebral vessel burst at that time? A similar question has to be dealt with in the case of pulmonary haemorrhage, which, as is well known, is frequently nocturnal in its incidence. The same applies to gastro-intestinal haemorrhages.

It is, of course, a matter of familiar knowledge that true angor pectoris occurring in the daytime is commonly associated with exertion or excitement involving raised blood pressure and an increased call upon the heart, the pain diminishing or passing off with cessation of the muscular effort or emotional disturbance, reduction of the blood pressure by amyl nitrite, etc. But it is also well known that anginal pain sometimes seizes the patient in the quiet

The results obtained in the present investigation lead to the conclusion that in considering the subject of sleep we have to deal with two distinct conditions, which have strikingly different associations as far as nervous, circulatory, respiratory, and other functions are concerned. (1) Undisturbed or sound sleep, attended by lowering of blood pressure, heart and respiratory rates, etc., and (2) disturbed sleep, modified by reflex excitations, dream, nightmare, etc., sometimes accompanied by extensive rises of blood pressure (hitherto not recognized), increased heart action, changes in respiration, and various reflex effects. The circulatory changes in disturbed sleep are something so very pronounced that it is somewhat remarkable that they should so long have escaped observation. So far as the present writer knows, the occurrence of marked rises in blood pressure during sleep has not even been suggested apart from the fact that no actual measurements have been recorded. No doubt paucity of opportunities and difficulties in observation have stood in the way. But the considerations as regards the occurrence of haemorrhages, etc., in the night (stated in the earlier part of this paper) give distinct indications of the probability of important blood pressure changes being present in some instances.

*Disturbed Sleep.*

In connection with the circulatory and the other phenomena of disturbed sleep there are various categories with regard to the degree in which the subject is able to recall his dreams or is conscious of the disturbances attending awakening. 1. There is no recollection of the disturbed sleep or dreaming condition, though the presence of such was clearly shown by observations on the sleeper—occurrences of muttering, talking, groaning, movements of the face, fingers, etc.; reflex disturbances were evidently active and pronounced degree.

2. On awakening there is a sense of the sleep having been uncomfortable and troubled, but there is no recollection of dreaming having occurred.

3. The fact of dreaming is remembered, but not the definite sequence of the dream.

4. Vivid dreams remembered in great detail.

In all the above categories cardio-vascular disturbances etc., have been recognized in more or less marked degrees. These disturbances disappear at various periods after awakening—often in a variable number of minutes.

*Distribution of the Changes in Disturbed Sleep.* The incidence of the recorded disturbances upon the various systems varies widely in different instances. The heart's action may be specially affected by the impinging of nervous impulses on the cardiac regulating centres in the medulla, etc. There may be much acceleration of the pulse with comparatively little elevation of arterial pressure; there may be a strong cardiac impulse with or without sensations of palpitation.\* On the other hand, in contrast with the above, there are cases in which the heart's action is not affected, there is a marked depression of the pulse, and without evidence of any marked acceleration of the pulse from the development of abnormal rhythm, etc. In such cases, as described in this paper, such acceleration is due to the preceding period of sleep in the earlier part of the night, according to modern theories which have been repeatedly ascertained to be correct.

often followed by pulmonary fibrosis. In British Guiana autopsies on 926 old malarial patients showed that chronic nephritis was present in 40 per cent. The suprarenals may be disorganized by true "parasitic emboli," leading to symptoms resembling Addison's disease. Hesnard describes the various lesions of the central nervous system and states that peripheral neuritis is an important sequela. Mental complications include manic-depressive insanity and certain forms of dementia præcox. Sabrazès described four cases exhibiting meningo-encephalitic symptoms. Claude (Paris) cited cases of malaria followed by lesions of the central nervous system.

#### 429. Febrile Infection in the Treatment of General Paralysis.

SANTANGELO (*Rif. Med.*, October 8th, 1923, p. 970) speaks very favourably of the treatment of dementia paralytica by the induction of fever. The usual method used by him is to inject into the veins of the patient some blood taken from a malarial subject during the febrile access. He also rubs some of the blood into the scarified skin. Down to May, 1921, 130 cases, recent and old, had been treated. Of these, 42 showed a complete remission, 58 more or less complete, and 30 unchanged. According to Weygandt and Kirschbaum, using the same treatment, they obtained 68 per cent. good remissions, 26 per cent. indifferent, and 12 per cent. negative. Lately the author has used a typhoid vaccine injection to produce fever in place of the malaria, with better results. Even allowing for the fact that spontaneous remissions in the course of dementia paralytica are well known, the author considers that his results were such as to encourage a further trial of the treatment.

### Surgery.

#### 430. Chronic Ulcerative Colitis in Childhood.

H. F. HELMHOLTZ (*Amer. Journ. Dis. of Children*, November, 1923, p. 418) describes five cases of chronic ulcerative colitis in children, characterized by chronic recurring dysentery with watery and bloody stools, much emaciation, persistence in spite of treatment, and without any known etiological infection. From a study of the cases the ulceration appears to commence, and to be most marked, in the rectum and lower sigmoid until the entire colon, and, more rarely, the ileum also, become involved. The x rays show marked narrowing and absence of haustrations of the portions of the bowel affected. The stools, usually from five to ten a day, contain a large amount of mucus and blood, frequently in clots. Though large haemorrhages occur only occasionally in adults, in children they are more frequent, and the passing of clots unmingled with mucus is characteristic. Emaciation becomes extreme owing probably to the toxæmia and the rapidity of the passage of the food, but in the absence of complications there is usually no fever. Prognosis is bad because of the obstinate persistence of symptoms under medical treatment by saline irrigations and large doses of bismuth, though recently improvement as the result of massive doses of iodine by mouth has been reported. If the patient is no better after two months' treatment upon medical lines, ileostomy with the establishment of a complete faecal fistula, as recommended by Brown, is advisable, so that the colon may be irrigated through the lower loop. A considerable time should elapse before the ileostomy opening is closed. The operative mortality is 50 per cent., but without operation the condition is almost certainly fatal.

#### 431. Acute "Non-gonorrhoeal" Urethritis.

E. BJÖRLING (*Acta Dermato-Venerologica*, vol. iv, fasc. 2, 1923, p. 277) discusses the etiology of those cases of acute urethritis in which no gonococci can be found in the discharge, and there is no evidence of chemical or mechanical injury. He has recently observed as many as eighteen such cases in the male, and in every case a careful investigation of the history, or an examination of the woman with whom the patient had been cohabiting, left little doubt in the author's mind that the urethritis was nothing but gonorrhoeal. With regard to the patient who states that he has never suffered from gonorrhoea, it may sometimes happen that he is speaking in perfect good faith, for, unless a posterior urethritis sets in, a gonorrhoeal anterior urethritis may occasionally—very seldom—run a perfectly symptomless course, the patient recovering from it temporarily without knowing that he has suffered from it. Bacteriologically negative cases are apt to be refractory to treatment, the reason for this being, in some cases, that the person with whom the patient is cohabiting is the source of infection and is not being treated. The evidence collected by the author constitutes a powerful argument against the facile

assumption that when a man is treated for gonorrhoea and gonococci can no longer be found in the discharge he is cured although he still has a so-called "post-gonorrhoeal catarrh."

#### 432. Whitehead's Operation for Haemorrhoids.

A. DZIALOSZYNSKI (*Zentralbl. f. Chir.*, November 3rd, 1923, p. 1630) states that recent inquiries have shown excellent results following this operation, in spite of the adverse reports published in American and English journals during the last three or four years. Gordon-Watson, Wilkie, Hirschmann, and others have stated that Whitehead's operation is frequently followed by stricture, prolapse of anal mucosa, and incontinence. The author holds that all these may be avoided by careful attention to technique. In the majority of his cases he obtained healing by primary union, but in other cases of secondary union the ultimate result was quite as good. In nine cases of annular excision he had no secondary stenosis. He claims that by careful suturing of the skin of the anal margin to the corresponding edge of the mucosa bleeding is arrested and primary union results in the majority of cases, there is no stenosis, nor ectropion of mucosa, and any incontinence is transient. His results confirm those of Hadda, Völker, Träger, and O'Connor, and go to show that, while ligation of circumscribed haemorrhoids may suffice, Whitehead's operation is best for severe cases. The author has seen no cases of secondary haemorrhage, post-operative abscess, nor fistula following this operation.

#### 433. Acute Perforations of the Stomach and Duodenum.

C. L. GIBSON (*Boston Med. and Surg. Journ.*, September 27th, 1923, p. 425) emphasizes the importance, in perforated ulcers, of prompt diagnosis, leading to early operation, with the possibility of cure. Time cannot be spared, and in order to save life by doing an early operation the surgeon must reconcile himself to an occasional mistake. The diagnostic points in this condition are a previous gastric history, the sudden onset with collapse and typical abdominal findings, referred pain, commonly seen in the left supraclavicular fossa—this comes on shortly after the original pain and usually does not last long—and the presence of free air in the abdominal cavity, shown by the x-ray picture. Patients operated upon within the first eighteen hours have a good chance of getting well; after twenty-four hours they stand little or no chance. Prior to administering the anaesthetic the patient is given a drink of water coloured with methylene blue, which helps to find the perforation quickly. Drainage after operation is rarely employed. Gastro-enterostomy may be justified in early cases; the author has only performed it once. The number of people who develop symptoms later and require a gastro-enterostomy for stenosis at or near the pylorus is surprisingly small, probably about 10 per cent. The routine use of gastro-enterostomy may result in an unnecessary death, or in certain complications, such as gastro-jejunal ulcer, which are inherent to the operation. The end-results in Gibson's series of 76 cases were most satisfactory; most of the patients reported themselves free from symptoms and in better health than before the operation.

#### 434. Treatment of Empyema.

V. H. VON CSAKANYI (*Zentralbl. f. Chir.*, November 10th, 1923, p. 1672) states that from January 1st, 1914, to September 1st, 1921, 97 cases of empyema were operated on in the second university surgical clinic at Budapest, with a mortality of 13.5 per cent. The etiological classification of the cases was as follows: traumatic, 9 cases; metapneumonic, 33 cases; metastatic, 4 cases; following pulmonary gangrene, 3 cases; abdominal disease, 1 case; mixed infection with tuberculosis, 17 cases; and post-influenzal, 30 cases, among which the mortality was 7.6 per cent. In 9 cases of chronic empyema resection of the thorax was carried out according to Schede's method. Conservative methods were ineffective in the treatment of acute or chronic empyema. The best results were obtained by free opening of the thorax, resection of the ribs, and drainage. Early operation was most satisfactory, even in the case of influenza patients. Schede's operation always yielded good results in chronic empyema, and the patients stood the operation well.

#### 435. Cerebral Puncture for Intracranial Pressure.

H. C. JACOBÆUS (*Acta Med. Scand.*, October 4th, 1923, p. 666) has made use of cerebral puncture for diagnostic and therapeutic purposes during the past few years at the Serafimer Hospital in Stockholm, and has had some cases which show that this procedure and Dandy's ventriculography may have an important future. One of his most instructive cases was that of a man, aged 56, suffering from haemorrhagic pachymeningitis, who showed all the signs of hemiplegia with greatly impaired mental faculties. There was a history

[illegible]

So far as the rupture of a weakened cerebral artery is in question the hydrostatic factor in the recumbent position is an added consideration; the weight of the column of blood between the levels of the head and the heart, which reduces the cerebral artery pressure in the standing position, is now largely out of action; with a given aortic pressure the pressure in a cerebral artery is naturally higher by a very appreciable amount (varying according to the elevation of the head) in the recumbent than in the erect posture, and the danger of a cerebral hæmorrhage during a rise of aortic pressure is necessarily increased.

The subjects examined were persons mostly between the ages of 50 and 65, all, so far as was known, without organic disease of the circulatory system. The observations were made quickly after the awakening of the subject, the apparatus having been kept in readiness for immediate use. Systolic blood pressure was measured by the auditory and tactile methods, diastolic pressure by the auditory method. On occasions, when no measurements could be made on convincing evidence of the occurrence of extensive changes was obtained by ordinary digital examination of the arteries, palpation of the carotid impulse, etc. The following are some of the examples of the sort of observations made and the nature of the results obtained.

The extent and intensity of the functional disturbances which may be set up during troubled sleep and the dreaming state are remarkable, though quite intelligible in view of the diminution of the control normally exercised in the waking state by higher neural mechanisms, which come to be more or less completely in abeyance during sleep; released from such control the lower mechanisms are apt to give exaggerated responses to the stimuli which would have comparatively little effect in the daytime. They affect impulses (somatic or visceral) which would still have only slight and quite different effects in the waking state may call for a complete and pronounced reflex responses. The influence of different impulses in provoking and shaping the course of dreams need not be emphasized. Potent in this respect are impulses from the viscera which in the waking state would only be productive of slight sensations—torture, headache, nausea, etc.; in sleep exaggerated responses may be set up, especially when numerous repeated perturbations have been acting in conjunction with the resistant effects of both cerebral and autonomic innervation—excitation of sympathetic, etc.

The effect of walking upstairs (twenty steps) was compared in this person with the disturbances occurring in sleep. The pulse rate was raised from 80 to 90-95, the systolic from 120 to 140, and the diastolic pressure from 80 to 90; the observations were made while the ascent was being continued, not after its cessation. Ordinary walking exercise on a fairly level road caused comparatively slight changes in the heart rate and the blood pressure. In the same subject some days previously a trip of 150 grain hypodermically raised the pulse rate from 81-82 to 130, with systolic and diastolic pressures of 135 and 75-80 respectively, as compared with 115 and 70 before atropine. Abdominal straining (expulsive efforts) raised the systolic blood pressure only a few millimetres.

It is evident that in this individual the stress on the circulatory system was vastly greater during such disturbed sleep as is described above, than under the conditions of ordinary easy life with avoidance of sudden violent effort, emotional excitement, etc. The actual height of pressure attained during the disturbed sleep was, no doubt, decidedly higher than as measured after awakening when it is declining with some rapidity.

*Subject No. 1.*

of severe headaches during the previous fortnight. Cerebral puncture over the right frontal tuberosity at the root of the hair yielded, when the point of the needle was at the level of the dura mater, about 10 c.cm. of brown viscid fluid which coagulated at once. The patient felt much better after this operation, but the improvement was not maintained, and twelve days later cerebral puncture was repeated, 10 c.cm. of blood-stained fluid being withdrawn. Rapid improvement followed, and the patient was ultimately discharged as cured. This is, so far as the author knows, the first time that such an experiment has been made, and he suggests that if a pachymeningeal extracerebral haemorrhage may derive great benefit from puncture and aspiration the intracerebral haemorrhage of an ordinary hemiplegia may also benefit therefrom.

## Radiology and Electrology.

### 436. The Action of X Rays in Cancer.

E. HASSENCAMP (*Zentralbl. f. Inn. Med.*, August 11th, 1923, p. 513) reviews the present position of this question, observing that the optimism so prevalent a few years ago has largely given way to an attitude of uncertainty. For successful irradiation of cancer the author observes that rays of sufficient hardness must be employed in order that it may be unnecessary to alter the proportion of the mixture of rays in their passage through the tissues; the rays will then be qualitatively homogeneous. These homogeneous rays must, as far as possible, be equally distributed throughout the irradiated area. These are the two rules of qualitative and quantitative homogeneity, first propounded by Dessauer, which regulate the present-day practice. The principles governing this are: (1) Production of very hard rays. A tension up to 250,000 volts is now used; higher voltages are technically possible but are unnecessary. (2) Filtration of the injurious soft rays by appropriate filters (zinc, aluminium, copper). (3) Increase of the distance of the tube from the body, when the increasing distance would lessen the difference of intensity of the rays in the deeper parts. (4) Irradiation of different areas from varying angles (cross-fire) in order to increase the penetration of the rays. In addition to the lessened penetration, due to absorption, it is known that some rays are deflected (this is proved by the softening of the outlines of bones and other deep structures in ordinary skiagrams). Formerly it was believed that in order to destroy cancer cells it was only necessary to produce a sufficient quantity of hard rays, and for this purpose more powerful apparatus was constructed. Now it is realized that the problem of the action of x rays on cancer has a biological as well as a physical side—that radio-activity depends on the degree of radio-sensibility found in various cell types. The lesser the degree of differentiation of a cell the greater is its reproductive power. Two antagonistic views are held by the German authorities: (1) that x rays destroy the nuclei of cancer cells; (2) that x rays stimulate the growth of connective tissue, which kills the cancer cells by compression. The author prefers to estimate the dose by its effects on the skin—that is, after the optimum dose, erythema appears in about eight days, followed by a bronzing of the skin (in about four weeks). At a discussion in Heidelberg last May none of the surgeons regarded irradiation as a substitute for operation. On the question of post-operative irradiation opinion was divided; one-half of the speakers considered that it induced more frequent recurrences, while the others stated that these had been lessened by subsequent irradiation. In some cases, especially those of rectal cancer, it was stated that irradiation had produced sufficient improvement to permit operation in cases previously considered inoperable. The gynaecologists were more optimistic and recommended post-operative irradiation in every case, although some failures were recorded. Hassencamp remarks that the anatomical relations of the uterus and the possibility of comparatively early diagnosis prevent comparison of these cases with carcinoma situated elsewhere. He emphasizes the point that x rays are not a specific cancer remedy.

### 437. Intratracheal Injection of Lipiodol in Radiography of the Lungs.

E. SERGENT and P. COTTENOT (*Journ. de Radiol. et d'Électrol.*, October, 1923, p. 441) refer to the great difficulty experienced hitherto in the interpretation of skiagrams of the lungs, due to the various structures and tissues, differing but little as regards translucency. The network of blood vessels and of bronchial tubes is so intricate that it is often difficult to distinguish one from another. Sicard and Forestier introduced the method of intratracheal injection of an oily solution of iodine, which is very opaque to x rays and is well tolerated. It may be injected through the glottis or through the crico-

thyroid membrane; the authors prefer the latter route. After puncturing the crico-thyroid membrane with a curved needle, of a calibre equal to that used in lumbar puncture, the patient is told to blow; if the needle has entered the tracheal lumen mucus escapes through it. To obviate paroxysmal cough the interior of the trachea is anaesthetized with a 2 per cent. solution of cocaine and the lipiodol injected slowly, the patient being placed in such a position that the solution will gravitate to the portion of lung which it is desired to examine. The usual quantity of lipiodol required is 20 c.cm., but as much as 40 c.cm. has been injected without inconvenience in cases where a large cavity had to be filled with the opaque oil. The authors have had no serious accident following the filling of the trachea and bronchi with lipiodol, nor have others who have used this method recorded bad results. Elimination of the oil is usually rapid; in three or four days very little remains, although in some cases traces have been found three or four months after injection, and some patients exhibit transient symptoms of iodism. Sergent and Cottenot claim that this method has furnished valuable information about the normal anatomy of the respiratory tract, and that in pathological conditions it has demonstrated the following abnormalities: (1) deviations of the trachea and bronchi; (2) changes in permeability of a bronchial area; (3) dilatation of bronchi; (4) pulmonary cavities; (5) bronchial and pleural fistulae. Cases descriptive of these conditions are recorded, and some remarkable skiagrams, illustrating bronchiectasis, cavitation, pulmonary fibrosis, etc., are appended.

### 438. Observations on Radium Dermatitis.

M. S. THOMSON and C. P. G. WARELEY (*Arch. Radiol. and Electrother.*, October, 1923, p. 153) find that radium and x-ray dermatitis are indistinguishable histologically and clinically but for the subungual hyperkeratosis found in the former. They also point out that the condition produced on the skin by prolonged exposure to the sun's rays is clinically identical with radium dermatitis, but that, curiously enough, the warts present in such cases are most rapidly influenced by exposure to 4/5 P.D. x rays. The similarity of radium and x-ray dermatitis is to be explained by the fact that the gamma rays of radium adjoin and overlap the x rays in the spectrum. The authors present in detail an account of a case of radium dermatitis. The patient had been exposed to the action of radium for nine years before he noticed a little roughness of his hands with a tingling sensation in the fingers. Continuance of exposure for a further three years produced discoloration of the hands with fissuring and extreme friability of the nails, and, four years later, warts appeared and have gradually increased in number. At the time of writing the skin of both hands was atrophic, thin, dry, and wrinkled; there were small scattered patches of brown pigmentation and numerous small hyperkeratoses but no ulceration. The nail-bed was much thickened at its free edge, this being characteristic of radium dermatitis; chronic periostitis of the phalanges was also present and was revealed by the x-ray picture. Histologically there was chronic inflammation with evidence of early but unmistakable carcinomatous infiltration of a squamous-celled type, and an important feature was the excessive destruction of elastic tissue, which in places was absent, and when present was seen only as short twisted fibrils.

## Obstetrics and Gynaecology.

### 439. Oesophageal Stricture after Pregnancy.

P. P. VINSON (*Amer. Journ. Obstet. and Gynecol.*, September, 1923, p. 346) adds three to the six cases which he has recently recorded of stricture of the oesophagus following pregnancy. The first patient suffered from uncontrollable vomiting during the eighth and ninth months of gestation; four months after induction of labour gastrostomy had to be done on account of increasing dysphagia. The second patient, who had renal insufficiency and some toxæmia, vomited almost incessantly during the last week preceding and the three weeks following labour; dilatation by bougies sufficed to cure the oesophageal stricture, which was noted four months after delivery. There had been copious haematemesis. The third patient died, probably from oesophageal haemorrhage, four days after instrumental dilatation of a stricture noted six months after parturition; there had been much vomiting during pregnancy. The cause of the stenosis of the oesophagus is to be found, according to the author, in pernicious vomiting associated with pregnancy, and a digestion by regurgitated gastric juice of the lining of the lower portion of the oesophagus; in the history of the majority of cases vomiting of dark material containing blood and burning substernal or epigastric pain are recorded.

10.20 .....	76	120	70	50

Subject in bed in afternoon. While asleep he had lain on the right side with the right arm pressed on by the head so that the right radial pulse was abolished. The left radial pulse was found to be very fast and the artery large and strikingly tense, immediately after waking; these unmistakable evidences of an exaggerated rise of blood pressure speedily passed off. The deepened respiration having been under the influence of the nightmare, with the illusion of his lying prone near the door of a house while he heard a visitor approaching along the drive; he had vivid and distressing sensations of intellectual efforts to rise. The nightmare was no doubt determined by the posture, the pressure on the arm, and the ischaemic condition. After awakening numbness and tingling were felt in the right arm, while the radial artery became very large and the skin flushed—evidence of after-effects of the ischaemia.

A subject, who had some symptoms of gastro-intestinal disturbance but was pursuing his usual avocations, had in the course of a night of broken sleep a dream in which he felt very restless at the irritating conduct of an official on a public occasion—a vivid dream but not distinctly a nightmare; there was no sense of fear, oppression, intellectual effort, etc. On his awakening it was found that there was no sense of palpitation, no sweating, no subjective alteration in respiratory sensations, no marked change in the respiratory movements was observed. But the cardiac impulse was greatly increased in force and fell over a larger area than usual in this period. The pulse was accelerated from a normal rate of 70-80 to 90-95. But the most notable change was a greatly raised blood pressure of 100-80 to 150-80, as shown by digital examination of the radial; the arteries were large and tense, obliteration difficult, and the range of the pressure variations at each beat palpably large. When examined fifteen minutes later these altered conditions were practically gone, which were not clearly remembered. Similar phenomena, in which some at least pronounced degree, were recognized; these virtually disappeared in a few minutes.

In one dream systolic pressure rose from 150 to over 200.

*Emotion, Motor Effort, and Gastro-intestinal Disturbance.*

While the most striking cardio-vascular effects are naturally present in dreams with a strong emotional content, it is to be noted that a vivid dream of active movement (cycling, for example) without sensations of night-

There is an instance of this kind the pulse tension was greatly increased and the pulse pressure was extensive while the heart rate remained at 72-75; the elevation of blood pressure was evidently brought about mainly by vaso-constriction.

It is noteworthy that the amount of disturbance (circulatory, respiratory, etc.) associated with vivid and alarming dreams varies greatly in different individuals and even in the same individual under different conditions; the effects are sometimes remarkably slight in the case of dreams that are at other times attended by very pronounced effects of the kind described above. There is reason to believe that the presence of some gastro-intestinal disturbance at the time may sometimes play a part in facilitating the development of the more marked effects on circulation, respiration, etc.

*Dangers of the Circulatory Disturbance.*

These cardio-vascular changes, involving sudden demands on the heart's power with great alterations in its rate and force and a steep and sometimes very extensive rise in blood pressure, are quite harmless in the healthy individual. Vivid dreams, involving hurtling to catch trains, etc., with failure to do so, are common in many persons and sometimes persistently recurrent—with no injurious consequences apparently. But the case is obviously very much otherwise with a damaged vascular system. If the going on under conditions which afford only a narrow margin of safety. There may be a myocardium abnormal in certain functional respects, whether or not these be attended by recognizable structural alterations with or without obvious coronary lesions, giving a susceptibility to ventricular fibrillation, or, on the other hand, a defective arterial tree with localized weakening (by military aneurysms, etc.) in the brain vessels, tuberculous damage in the lungs, ulcerative conditions in the gastro-intestinal tract, etc.; where haemorrhage may readily be determined. In a heart susceptible to fibrillation a rapid call on the heart during muscular exertion may be determined. In a heart susceptible to fibrillation a turbulent condition of sleep and dreaming a similar mechanism is sometimes brought about and strongly into action—diminution of or loss of vagus control and, especially under emotional stress, stimulation of the cardiac sympathetic together with a high blood pressure—conditions which favour ventricular fibrillation.

A possible discharge of adrenaline into the circulation under emotional excitation also comes into question, though the importance of such discharge or its existence has been denied by Stewart and Kogoff, in opposition to the well known work of Cannon and de la Paz. The time incidence of attacks of anginal pain may obviously be determined by similar conditions.

It is clear that the foregoing facts must be taken as profoundly modifying the former conception of night as the time of rest, and sleep as a condition in which quiescence prevails and recuperative changes go on, restoring the body and mental capacities which have become more or less reduced at the end of the hours of work and wakefulness—a period of repose also attended by sedative and beneficial effects on many morbid conditions. This conception, while true as regards undisturbed or sound sleep, has to be qualified by the consideration that night and sleep are occasionally the seasons of acute effects due to emotional disturbances which, in the peculiar conditions present, induce very formidable effects upon the circulatory system, throwing a formidable strain upon its weak points, whether these be cardiac, with susceptibility to fibrillation or anginal pain, etc., or arterial, with risk of rupture.

In this way the individual may, during the nocturnal period of assumed repose, be subjected to suddenly developed stresses, as estimated by the rise of blood pressure (even as the arteries are relaxed when it is falling) and the expenditure of increased heart action, far beyond what is involved in ordinary muscular exercise gradually initiated—for example, walking, cycling, slow ascent of stairs, swimming, or mental excitement in certain degrees. Thus haemorrhages, the

**440. Tubal Pregnancy.**

F. VOZZA (*Annali di Ostetricia e Ginecologia*, September, 1923, p. 470) publishes from the Milan Clinica Ostetrico-Ginecologica figures with regard to the etiology of tubal gestation. The cases of this condition treated from 1906 to 1922 numbered 606, or 1 per cent. of the total admissions; only 7 were aged less than 20, and only 14 more than 40. There were 114 nulliparae and 74 unmarried patients; 31 per cent. had had one or more abortions. With regard to antecedent pelvic inflammatory disease as an etiological factor, Vozza notes that there was a history of gonorrhoea or of infection following childbirth or abortion in 90 cases. Among the 437 patients who were operated on by the abdominal route, no fewer than 62 showed well marked inflammatory disease of the adnexa of the opposite side to that of the ectopic gestation. All but one of the 21 patients who had been previously treated in the clinic had received such treatment for intrapelvic inflammation of some description. About one-sixth of the patients had been curetted some time before the occurrence of tubal pregnancy. Morbid conditions of one or both ovaries, apart from the tubes, were encountered in 7 per cent. of laparotomies. Recurrence of ectopic pregnancy was noted in 15 patients, and in 2 there was a coexistent uterine gestation; in two instances both tubes contained a gestation sac. Pregnancy in the interstitial portion of the tube was noted once only; the most common; the next in frequency b..., which seemed to be associated often with early rupture and abundant internal haemorrhage.

**441. Treatment of a Myoma during Pregnancy.**

O. A. BOJE (*Finska Läkarsällskapets Handlingar*, September-October, 1923, p. 530) finds that the problem whether a uterine myoma complicating pregnancy should be treated conservatively or by operation has often to be considered, for myoma of the uterus is common in the child-bearing age and is seldom the cause of sterility. It is seldom necessary to operate on a myoma during pregnancy, but there are three indications for surgical interference. (1) The myoma may prevent the normal progress of pregnancy; (2) it may threaten to be a mechanical obstacle to the completion of labour; and (3) it may cause unbearable pain, with or without signs of peritonitis, threatening severe complications. The author records four cases, in all of which he had to operate during pregnancy. In every case convalescence was uneventful, the pregnancy went to term, and labour and puerperium ran a normal course. In one case a myoma, weighing 1,450 grams, was attached by a thick pedicle to the fundus of a fifth-month pregnant uterus. In another case there was an intraligamentous cervical myoma, of the size of a fist, which had already displaced the uterus in the third month of pregnancy. In the third case a rudimentary uterine horn was studded with myomatous nodules; the uterus was deeply fixed in the pelvis by adhesions, and was in the third month of pregnancy. In the fourth case, also in the third month, there was a myoma, weighing 240 grams, in the anterior wall of the uterus, where it had given rise to pain and vesical tenesmus. The author's study of the literature of this subject has confirmed his own experiences; with the present highly developed operative technique it is seldom that the removal of a myoma from a pregnant uterus induces abortion or premature labour.

**Pathology.****442. Rat Leprosy and its Transmission to Man.**

MARCHOUX (*Paris médical*, October 27th, 1923, p. 313) is convinced that there is more than a simple analogy between human and rat leprosy. The rats in the sewers of Paris are heavily infected, the organism resembling *B. leprae* and having the same distribution and mode of spread. The lesions are tubercular; masses of the organisms are found in cutaneous nodules and in the lymphatic glands draining the area, later in the liver and spleen. The disease can be transmitted to laboratory rats and mice by direct contact. The case is recorded of a leper in the Pasteur Hospital with cutaneous patches from which a short acid-fast bacillus with fragmented protoplasm was obtained. *Post mortem*, masses of these bacilli were found in the lymphatic glands, liver, and spleen. Rabbits, guinea-pigs, and rats were inoculated with the splenic pulp. The two former animals were unaffected, but five rats out of six contracted a disease indistinguishable from rat leprosy, which has since been successfully transmitted to four generations of laboratory rats. The author holds that inoculation in the reverse direction, from rat to man, should be equally successful, and that the bacilli of human and of rat leprosy are types of the same organism, resembling in this respect human and bovine types of the tubercle bacillus.

**443. Anomalies of Intestinal Rotation.**

N. M. DOTT (*British Journ. of Surg.*, October, 1923, p. 251) points out that during development the alimentary canal may suffer a large variety of perversions. The three stages of normal embryonic intestinal rotation are described. In the second stage the essential disposition of the intestines is attained. Errors occur most commonly in the disposition of the midgut during the second stage, and the cause suggested is variation in size of the embryonic umbilical orifice. During the second stage of rotation the midgut loop is returned to the abdominal cavity through the narrow umbilical orifice. This reduction may be made more difficult or more easy by the size of the orifice leading to disorderly reduction, and it is suggested that on this depends the cause of failure or complete reduction. Abnormal disposition of the intestines leads to abnormal attachments or fixation. The former may lead to interference with motility, kinks, and compression; the latter predisposes to ptosis, torsion, or volvulus. The characteristic pathological consequence of anomalous rotation is failure of efficient fixation and secondary volvulus, and during the first few days of life volvulus may occur and is of a very extensive type. In later life volvulus of the ileo-caecal region is the typical lesion. Three cases are recorded which led to volvulus with acute intestinal obstruction as the result of anomalies of intestinal rotation. The diagnosis of anomalies of intestinal rotation is considered from the standpoint of abnormally situated appendicitis, from the point of recognizing the condition on the operating table, and in cases of secondary volvulus in the newborn. An operative treatment by reduction and fixation in extensive volvulus of the newborn is suggested.

**444. The Relation of Deprivation of Vitamin B to Bacterial Infection.**

EXPERIMENTS carried out by G. M. MARSHALL (*Journ. Path. and Bact.*, October, 1923, p. 485) show that one of the effects in pigeons of a dietary deficient in vitamin B is to render them more susceptible to bacterial infection. Ten pigeons which had been fed for from twenty-five to thirty-five days on a diet lacking in this food factor were inoculated intraperitoneally with 3,000 million pneumococci Type 2. All died within thirty-six hours, and *post mortem* the organism was recovered from the heart blood and the peritoneum. Ten control birds fed on oats, receiving the same dose, all recovered. An endeavour to explain the mechanism of this effect showed that in the experimental pigeons there was a considerable lowering of the body temperature; whereas the temperature of the control birds varied between 41.6° and 42.4° C., that of the pigeons fed on the vitamin-deficient diet was only 38.4° to 39.8° C. Following up this clue they found that it was only necessary to lower the body temperature by means of an antipyretic such as pyramidon to produce a similar diminution in resistance to the pneumococcus. Similar experiments repeated with the meningococcus, with *B. coli*, and with *B. enteritidis* gave the same results. The pigeons fed on the experimental diet had a lowered temperature and a low resistance to infection with these organisms. The authors conclude that the lowering of the body temperature appears to decrease the resistance by facilitating the growth of the invading organisms, by reducing the leucocytic response to the infection, and by diminishing the bactericidal power of the leucocytic exudate.

**445. An Inoculable Virus in Post-encephalitis.**

J. A. SICARD, J. PARAF, and L. LAPLANE (*Bull. et Mém. Soc. Méd. des Hôp. de Paris*, October 18th, 1923, p. 1338) report the presence of an inoculable virus in the cerebral nuclei four years after the initial symptom. The patient, a female, aged 55, had encephalitis, with stupor and diplopia, in March, 1919. She recovered in a month and, except for great weakness, kept well for six or seven months. Then symptoms of Parkinson's disease developed—rigidity, the characteristic mask, and later twitching of the fingers. In spite of treatment she got progressively worse, reached a state of coma and marasmus which necessitated artificial feeding, and died on July 13th, 1923. A portion of the grey matter of the mesencephalon was broken up in normal saline and inoculated into the brain of six rabbits, two of whom, further, had the material introduced into the anterior chamber of the eye. Four of the animals died in forty-eight hours of acute encephalitis, the other two on the thirteenth and fifteenth days with coma, emaciation, and paresis of the left hind limb. The toxicity of the virus was not impaired by continued passage through the brain of three more groups of rabbits, fatal results being obtained in every rabbit inoculated in periods ranging from eight to thirteen days. Histologically the grey nuclei showed perivascular lymphocytic infiltration and zones of neurone degeneration—the characteristic findings in experimental encephalitis.

onset of arterial attacks, and other disturbances in the night due to ventricular fibrillation in most instances. In the light of these observations it is easy to understand how in certain circumstances death may come like a thief in the night to a susceptible person living with circulatory conditions that approach the danger line, though these conditions may, in favorable circumstances and barring fresh developments, be compatible with many years of moderately active life.

# AN INVESTIGATION INTO THE EFFECTS OF THE ARSENOBENZOL TREATMENT OF SYPHILIS ON LIVER FUNCTION.

H. MACCORMACK, C.B.E., M.D., F.R.C.P.,  
AND  
J. C. DODDS, M.B., B.S., B.Sc.,  
MEDICAL PATHOLOGIST TO THE MIDDESEX HOSPITAL AND LECTURER IN BIOCHEMISTRY IN THE MEDICAL SCHOOL.

ALTHOUGH salvarsan and its substitutes and modifications have now been in general use for a considerable number of years, syphilologists are not yet in complete agreement upon the method of using these remedies in the treatment of syphilis. Some, for example, rely entirely or principally upon salvarsan as a curative agent; others deem that it should be employed in conjunction with mercury or with the newer synthetical preparations. There can be no doubt, however, as to the advantages of this drug; but it is not one to be used recklessly, and of late, since its more extensive use, and since its employment in larger doses and in a greater number of injections, certain untoward results have become familiar to those working with it. Modern methods have largely succeeded in abolishing, or at least diminishing, the immediate dangers or inconveniences, such as fever; but there still remain two important and serious consequences attributable to its administration—arsenical dermatitis and jaundice. Doubtless among the first to call attention to the possible harmful effects of the arsenical compounds on the liver, regarding fatal cases of poisoning, was Dr. von Arsenobenzol compounds as essentially identical with poisoning by chloroform, ether, and phosphorus. In his experiments carried out with arsenical compounds in rabbits he found an interstitial hepatitis with injury to the parenchymal cells, and a nephritis in addition to the hepatitis. Many other workers have adhered to the possibility of serious toxic effects on the liver tissues, and indeed it would appear that these, with dermatitis, may now be regarded as being among the most common of the ill effects following the administration of the drug.

In considering the treatment of syphilis it has clearly to be kept in mind that cure may only be expected with any degree of confidence in the earlier stages of the disease; therefore in this early stage the powerful remedies available may be pushed to the degree of tolerance with justification. The problem presented to the dermatologist is twofold: first, he has to determine what amount of arsenical compound is required to give in the early or curable stage the best chance of cure; and, secondly, having decided this, he has further to consider whether this amount can be administered without risk of injury to the individual.

To the first part of the problem attention was paid by one of us and Kenaway in an earlier series of cases, and it was found that a series of ten injections of novarsenobenzol, amounting to 8.7 grams, satisfied the requirement in most cases—provided that treatment was subsequently continued with mercury. In view of the statements by competent observers as to the possible harm to the liver tissues from such a dosage, the present investigation was undertaken.

A series of 57 patients in different stages of disease, undergoing treatment with novarsenobenzol, was investigated, the liver functions being tested by methods to be described. It will be noted that the examinations were carried out both during and at varying intervals after salvarsan administration. This was done in order that the harmful effects, if any, could be determined not only during the period when the arsenical compound was being administered, but also at varying periods afterwards, when delayed harmful effects might occur.

The investigator of hepatic function is confronted at the outset with certain physiological facts which make evident to him the difficulty of his task. Thus, the work of F. C. Mann has shown that four-fifths of liver substance can be removed from an animal without occasioning any apparent adverse symptoms, apart from some temporary shock inevitable where so extensive an operation has been performed. If, however, more than four-fifths of liver substance be removed, the animal develops convulsions, which may be prevented, at least for some time, by the intravenous administration of glucose solution. This fact is extremely important; it corroborates the common observation, that even in cases of massive secondary carcinomatous deposit in the liver the only symptom of hepatic disturbance may be jaundice. There is evidently what may be termed an enormous "liver reserve," and this prevents any known test from being entirely satisfactory, because, unless a very large amount of liver tissue be put out of action, a single test may fail to give a positive reaction. We have attempted to overcome this difficulty by using a number of different tests.

The tests that may be employed to determine liver function naturally fall into certain groups which are designed to investigate particular functions. Owing to the nature of the chemical reactions in some of the tests it is often extremely difficult to read the result accurately; we have therefore selected the following as being the most likely to give reliable results. They are those depending on biliary function and those depending on the lipase content of the blood.

The first group is concerned with the investigation of bile pigments and their precursors, urobilin and urobilinogen. We may here briefly summarize the metabolism of these substances. As is well known, the liver secretes bilirubin and bilirubin into the intestines; there these pigments meet with intestinal bacteria and are by them converted into various substances, the most important, from the point of view of the tests employed, being urobilinogen. Some of this chromogen is absorbed into the blood stream, and is then picked out by the liver cells, converted into bile pigment, and re-excreted with the bile. A very little passes out into the urine. But if there be any damage to the liver cells this property of converting urobilinogen into bile pigment is lost, and therefore urobilin accumulates in the blood and is excreted in excess in the urine. Hence it follows that any excess of urobilin in the urine points to a damage of the liver cells, and the demonstration of such an excess may be accepted as evidence of liver defect. This phenomenon precedes the appearance of bile pigments in both blood and urine. The details of the tests employed to detect this substance are given later.

The tests depending on the lipase content of the blood are based upon observations by Whipple, who showed that after chloroform poisoning the lipase concentration of the serum was "cut out" of the circulation. He suggested the estimation of blood lipase as a test of hepatic function, and this method has been used in this country in especial by Mackenzie Wallis.

The technique employed in the different tests is as follows:

*Tests for Urobilin and Urobilinogen.*  
Ehrlich's aldehyde reaction: To 5 c.cm. of urine two drops of a 5 per cent. solution of para-aminoazobenzaldehyde in 50 per cent. HCl are added. If the test be positive, the resulting mixture becomes deep red. Occasionally it is necessary to warm the solution to bring about the reaction. This test.

## 1883 De Dion Bouton 1924

*Leave your Car Troubles with 1923.*

~~~~~

‘The year is going, let it go’ and your old car with it. Change it for a De Dion, the car that has served the Medical Profession so well during four decades. No car is so well suited to the Doctor. It combines driving comfort with running economy; speed and power with lineal beauty; and is of a quality that endureth.

On receipt of a p.c. we will furnish the name of our nearest agent. He will give highest market price for your old car; arrange, if desired, the new sale on payment from income, and advise and help you in the choice of colours and trimmings for your new De Dion.

*London Built Carriages. O.H.V. Engines. Four Wheel Brakes. Cantilever Springs. Wood or Wire Wheels. Complete Cars from £540.*

Illustrated Catalogue sent on request.

Key to Tests Employed: E. A. = Ehrlich's aldehyde test; U. = urubilin; H. = Hay; L. = iodine; Gm. = Gmelin; F. = Fouchet; L. = lipase. +, Positive; -, negative; ±, doubtful.

when positive, demonstrates the presence of a pathological amount of urubilinogen. Schlesinger's test for urubilin: 20 c.cm. of urine is acidulated with acetic acid and then the urubilin is extracted by inverting with 5 c.cm. of amyl alcohol. The amyl alcohol layer is pipetted off and a few drops of a 10 per cent. alcoholic solution of zinc chloride are added to it. If a green fluorescence develops the test is positive; in addition the characteristic spectrum can be observed. A positive reaction demonstrates an excess of urubilin. For the detection of bile pigments and salts the familiar—but unreliable as regards special purpose—Gmelin's, Hay's, and iodine tests were employed.

#### Tests for Bile Pigment in the Blood.

To demonstrate the presence of these substances we have employed Fouchet's test. This reaction is extremely delicate, but nevertheless very simple to perform. To three drops of serum three drops of the following solution are added: 5 grams trichloroacetic acid, 20 c.cm.  $H_2O$ , 2 c.cm.  $FeCl_3$  solution (10 per cent.). A white precipitate appears at once and if bile is present the precipitate so formed becomes greenish-blue, reaching its maximum degree in twenty minutes. It is claimed by the originator of this test that it is capable of giving a positive result in so high a dilution as 1 in 60,000. Our observations have confirmed its extreme delicacy and reliability.

#### Blood Lipase Estimation.

We employed the method of Lowenhardt. Into four test tubes 1 c.cm. of serum is placed, together with 0.5 c.cm. of toluene each tube, making the total volume 4 c.cm. To two of the tubes are incubated for eighteen to twenty-four hours in an

incubator at 37° C. At the end of this time the tubes are removed, and a drop of azolinin solution is added to each. The tubes containing serum alone are shaken, and are titrated with N/10 acid. The other tubes, in which the lipase have produced butyric acid, are acid in reaction, and are consequently titrated with N/10 alkali. The amount of lipolytic action is the sum of the mean amount of acid and alkali used. Normally, this is between 0.2 and 0.5 c.cm.

To be of value as evidence, any series of tests must satisfy two criteria: they must singly or in combination be capable of returning positive results when the defect they claim to demonstrate is present; at the same time they must be of such a nature that they do not give positive evidence where normal conditions exist. Hay's, the iodine, and Gmelin's tests failed to satisfy the standard of accuracy aimed at. On the other hand, we believe that Ehrlich's aldehyde test, Schlesinger's test, Fouchet's test, and the lipase test are trustworthy, as shown by the following investigations undertaken to test their reliability.

Negative controls were made on a series of sixteen students, and also on sixteen patients who had been admitted to hospital for conditions which did not involve the liver, and in whom, therefore, the liver functions might be assumed to be normal. In every case the tests as applied to the urine and blood gave negative results. This series of 32 cases indicates that the tests are so far reliable in that they do not give positive results where the liver is functioning normally. The group of positive controls fuller consideration; details are given below.

No Goods sent on approval.

Case I.—C. A., female, aged 50 years, under the care of Dr. Wynter. On admission the patient was jaundiced and presented a palpable mass in the left hypochondrium. All tests strongly positive. Post-mortem examination confirmed the diagnosis of a carcinoma of the gall bladder.

Case II.—Mrs. S., aged 60 years, under the care of Dr. Wynter. On admission slight jaundice, with enlargement of the liver. A diagnosis of cirrhosis of the liver was made and verified post-mortem. Here all the reactions were positive.

Case III.—D. B., (under the care of Dr. Izod Bennett). The patient was a heavy drinker and presented the signs of alcoholic cirrhosis with enlarged liver. All reactions positive, except Gmelin and iodine tests. Lipase 0.6.

Case IV.—H. R., aged 29 (under Dr. Cockayne). Enlarged liver; no jaundice. All reactions positive except Gmelin's and iodine tests. Lipase 0.5. Diagnosis, early cirrhosis.

Case V.—H. N., aged 22 (under Dr. Cockayne). Jaundice started when 15 and has continued. No symptoms. Liver enlarged. Fragility of corpuscles increased. Chemical diagnosis, Hanot's cirrhosis. All reactions positive. Lipase 0.7.

Case VI.—H. B., male, aged 8 (under Dr. Bennett). Three weeks before admission this child had acute catarrhal jaundice, but jaundice had practically disappeared when tests made; a slightly enlarged liver could be detected. All reactions positive. Lipase 0.5.

Case VII.—E. H., female, aged 65 (under Mr. Sampson Handley). Jaundiced when admitted and discolored gall bladder. At this stage all reactions were positive. After six weeks the jaundice and gall bladder distension had disappeared. All reactions were again positive at this stage except the iodine and Gmelin tests. Lipase 0.4.

Case VIII.—Male, aged 14 (under Dr. Bennett). Patient had severe indigestion and "felt ill." All reactions positive except the iodine and Gmelin's reactions. A week later the patient developed acute catarrhal jaundice. Lipase 0.5.

These eight positive controls are summarized briefly in Table II.

TABLE II.—Positive Controls.

We may now proceed to the examination of the series of 57 cases of syphilis where arsenians had been administered and where the liver functions were investigated by the methods already detailed. Table I summarizes the type of case, the amount of arsenical compound administered, the interval after commencing treatment when the liver functions were investigated, and the results obtained from the investigation. Four different groups may be identified: those where dermatitis occurred; those where jaundice developed; those where chemical evidence of liver defect was shown by the tests (without clinical manifestations); and those where the liver functions appeared to be normal. The last group, as will be seen, includes the majority of cases.

## I. Arsenical Dermatitis.

In this group are included five cases—1024, 1148, 1171, 1391, and 1459. Several observations may be made in respect of this group.

No. 1024 developed severe dermatitis after the seventh injection. The Wassermann reaction had become negative after the fourth injection, from which he completely recovered. The Wassermann reaction became negative after the fifth injection and remained negative for six months; it then became positive and remained positive in spite of continued mercurial injections carried on for some months. In this case the liver functions were investigated before the first injection.

No. 1171 developed dermatitis of moderate degree after the ninth injection, from which he completely recovered. The Wassermann reaction became negative after the fourth injection, from which he completely recovered. The Wassermann reaction became negative after the fifth injection and remained negative for six months; it then became positive and remained positive in spite of continued mercurial injections carried on for some months. In this case the liver functions were investigated before the first injection.

We have had the opportunity of testing the liver functions in five instances where jaundice followed the administration of novarsenobenzol. The tests were carried out at varying periods after the jaundice had manifested itself. The actual details may be summarized as follows:

No. 778, a female, aged 21 years, received 7.8 grams in ten injections, with subsequent mercurial treatment. Twelve months after beginning treatment the patient developed a mild type of jaundice from which she made complete recovery. Three months later the liver functions were tested and were all completely negative. In this case cure of the syphilitic infection would appear to have been effected, for the Wassermann reaction was negative two years and three months after first coming under observation.

No. 1209, a female, aged 30 years, received 3.6 grams of novarsenobenzol in six weekly injections. All the liver tests, except Hay's, were negative eight months later. The patient was probably cured, for the Wassermann reaction has remained negative, and a healthy child was born at the end of treatment.

No. 1251, a male, aged 35, suffering from tabes, received 7.8 grams of novarsenobenzol in ten weekly injections. He developed jaundice six months after the last injection. Here also all the liver tests were negative one year later—with the exception of Hay's test.

No. 1316, a male, aged 28 years, received 8.7 grams in ten weekly injections. Slight jaundice developed eight months after the first injection. In this case the liver tests were investigated in view of a series of negative Wassermann reactions obtained. It may be assumed that the syphilitic infection was cured while jaundice was still present and gave positive results (see Table I). The jaundice appeared—and were then completely negative. At this time, therefore, the liver functions were apparently normal. A complete recovery was made from the jaundice and an improvement also occurred in the tabes.

Jaundice is the most obvious and therefore the most frequently observed evidence of disorder of the liver following the administration of arsenian compound. But apart from this very obvious indication of a derangement of the hepatic function, it is possible for a disturbance to occur without any obvious indication of liver defect. In the most cases of jaundice, the liver functions are investigated after the jaundice has appeared, and are then completely negative. At this time, therefore, the liver functions were apparently normal. A complete recovery was made from the jaundice and an improvement also occurred in the tabes.

No. 1391 developed dermatitis after the second injection; there was complete recovery from this. The Wassermann reaction became negative seven months later. Seven months after commencement of treatment all reactions for liver function were negative. The subsequent history of this patient is not known.

No. 1459 developed severe dermatitis after the seventh injection of novarsenobenzol. She absconded herself from the hospital for eight months. On returning the Wassermann reaction was found to be negative. In this case the liver function was investigated three months after the beginning of treatment and gave positive results.

These five cases present certain interesting features. It will be seen that in three out of the five the Wassermann reaction became ultimately positive—an observation contrasting the general statement that where dermatitis occurs a continued negative Wassermann reaction is the rule. In only one case was evidence of disturbed liver function obtained, and it is noteworthy that in this case the investigations were made at the shortest interval after the administration of the arsenic. It would seem, however, that even if a disturbance of the liver is associated with dermatitis, such a disturbance is of a temporary nature and is followed by complete recovery of function.

It will be noted that in these cases the total amount of arsenical compound (novarsenobenzol) varied considerably. The cases in which severe dermatitis developed (1024 and 1459) each received 6 grams. On the other hand, dermatitis of moderate severity followed doses of 7.8 and 1.5 grams (1148 and 1391). It would therefore appear that the degree of dermatitis does not entirely depend upon the amount of the drug administered; indeed, the dosage in these cases is less than that given to the average patient in the clinic, where the drug is readily tolerated. The occurrence of dermatitis in two sisters treated at different times indicates that some individual idiosyncrasy predisposes to this form of eruption.

## A British Medical Association Lecture

OR

## HYSTERIA AND NEURASTHENIA.

DELIVERED BEFORE THE BLACKPOOL DIVISION,  
NOVEMBER 14TH, 1923,

BY

ERNEST S. REYNOLDS, D.L., M.D.LOND., F.R.C.P.,

EMERITUS PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY  
OF MANCHESTER; CONSULTING PHYSICIAN TO THE  
MANCHESTER ROYAL INFIRMARY.

ALTHOUGH the expression "functional nervous diseases" is a bad one (for do not all diseases during life declare themselves by alteration of function?), yet it is a well established term and is of use and should therefore not be lightly discarded; for it includes those affections in which we know of no pathological anatomic change and in which we assume that there is either some dynamic abnormality in a statically normal nervous system, or else that a lesion, if such exists, cannot be found owing to imperfect methods of examination.

Only a few years ago this group was a large one and included Landry's paralysis, myasthenia gravis, Graves's disease, chorea, paralysis agitans, epilepsy, tetanus, tetany, paramyoclonus, convulsive tics, spasmodic torticollis, habit spasm, writers' cramp, tic-douloureux, migraine, hysteria, neurasthenia, hypochondriasis, and so on. But in many of these affections definite organic changes are now recognized, and in others, even including neurasthenia, it is easy to conceive either that changes exist or that normal reflexes have become disorganized.

I wish here to deal especially with hysteria and neurasthenia. It is often assumed that the great war added enormously to our knowledge of these conditions. Certainly it led an increased proportion of medical men to take an interest in them and to study them for the first time; and this was an excellent thing. But I am not alone amongst neurologists in saying that the war revealed no manifestation of these affections in any way new to us, and no system of dealing with them which had not already been practised by those engaged in that branch of medicine. The war added very greatly to the already existing prodigious mass of literature on hysteria, neurasthenia, and the psychoses; but this is not an unmixed blessing, for it has enormously complicated a somewhat intricate subject, and, worst of all, has led to the introduction of a totally unnecessary new terminology, gradually becoming almost a foreign tongue, and often, to me at any rate, incomprehensible. Some authors, in fact, seem to have lost themselves in a forest of words. Yet in spite of this there is often an inability to distinguish between two entirely different affections—hysteria and neurasthenia—and worse still to mix up neurasthenia with the early manifestations of insanity, with which as a rule there is no connexion.

## HYSTERIA.

I will define hysteria as a purely mental condition without pathological anatomic change in which diseased manifestations are imagined and assumed; and the basis of the condition is a morbid craving for sympathy or notoriety, or both. Note that it must be a morbid craving and that it must be some diseased manifestation which is assumed. Many have a craving for notoriety which they try to obtain by writing to newspapers, speaking on all kinds of subjects at every opportunity, or dressing in bizarre clothing, and in some this craving so greatly influences their conduct as to make it morbid. But this is not hysteria, as it is not a simulation of disease. So with a craving for sympathy. This may be a very real and legitimate desire, as in the case of the sick or overworked wife neglected by her husband, which exhibits itself by depression or weeping. This is not hysteria; but if as a result of such craving for sympathy some diseased manifestation is assumed, then the craving is morbid and it is hysteria. In neuropathic subjects this craving for sympathy may occur without any reasonable cause for sympathy to be given, as when a servant has

been rebuked ever so gently by a master, for some slight fault, and a hysterical convulsion has resulted.

It may be objected that such an assumption of a diseased condition is mere malingering. I admit that sometimes it may seem difficult to make a distinction, but it is really very wide, for I define malingering as the deliberate assumption of a diseased condition, the basis of the assumption not being a morbid craving for sympathy or notoriety, but a natural desire for personal and material gain. Malingering is most common amongst prisoners (including suspected persons awaiting trial), soldiers and sailors (especially on active service), and in persons claiming compensation for injuries. In my presidential address at the Neurological Section of the Royal Society of Medicine<sup>1</sup> I narrated several pairs of cases in which the manifestations were similar, one case of each pair, however, being hysteria, the parallel case malingering. Let me narrate two illustrative cases.

A nurse complained of intense pain in the spine, worse on movement, and pyrexia up to 102° F. was present. She was, of course, kept in bed, but repeated examinations revealed no cause for her trouble; the pain and irregular pyrexia continued for several weeks. I then became suspicious, took her temperature myself with two thermometers simultaneously, one in each axilla, and found the temperature normal. She recovered at once, knowing her deception had been found out. Now if this simulated illness was for the purpose of obtaining the sympathy of her attendants and fellow nurses she was a case of hysteria; but if merely to have a lazy and comfortable time in bed it was malingering.

A boy, aged 16, was brought to me suffering from total blindness which had come on rather suddenly while at a public school. No cause could be found for this in the eye itself. He had to be led about everywhere, and one of his schoolfellows had always to attend him. When he came to see me I at once noticed from his features that he was "taking stock" of me. I took him in another room away from his friends, spoke rather sharply to him, told him he could see perfectly well, and ordered him to return to the other room and walk freely about to show his friends he had recovered, and this he did. If this blindness was assumed to get off lessons, and especially if he had been found reading novels when alone, he was a malingerer; if to gain sympathy and notoriety amongst his fellows, it was hysteria.

Both in hysteria and malingering any disease may be imitated which the person has seen or heard of or read about, but never one of which the person has no previous knowledge; and the greater the knowledge of the disease the more close the resemblance will be, and the contrary. In both cases an audience is necessary, a hysterical person does not waste her substance "on the desert air." A hysterical person, and even a malingerer, will submit to all kinds of personal discomfort (even the amputation of a limb) to gain the object in view.

One fundamental difference between hysteria and neurasthenia is that the former is principally a matter of objective physical signs, the latter of subjective symptoms. The manifestations of hysteria, such as blindness, deafness, mutism, anaesthesia, loss of power, vomiting, raised temperature, and so on, can be observed and tested by others; those of neurasthenia all relate to altered feelings. But in hysteria and in malingering complaint is sometimes made of intense local pain, and it is impossible to test the truth.

As regards etiology, all persons are prone to hysteria, and it is sometimes seen in domesticated animals, such as horses, and especially pet dogs craving for notice. Gilles de la Tourette<sup>2</sup> records several such cases. One was that of a terrier for whom his mistress got a bitch as a companion. The dog at once lost its gaiety and appetite, developed dysphagia, alteration of voice, and a progressive paraplegia without incontinence. It recovered as soon as the bitch was removed.

In neuropathic heredity this proneness is more likely to become manifest; in the well balanced person, in spite of all inducement, it will never occur. Almost to a day is exempt; I have seen hysterical cerebellar reel in a boy of 7 years, and hysterical flatulence from deliberate air-swallowing in women over 60. It is, of course, commoner in women, but is also found in males (generally below the age of 20). The immediate causes of the condition manifesting itself are almost too numerous to mention: moral shocks, jealousy, insults, either real or imagined disappointments, frights, and injuries; sometimes it occurs as a complication of real disease. But in every case, if thoroughly investigated, the basis is a craving for sympathy or

without jaundice. Such a defect can only be determined by special tests—for example, those we have already described in detail. While the incidence of jaundice may be used to indicate the degree of hepatic derangement from the arsenical substances, we believe better evidence can be obtained by employing special chemical tests for liver efficiency. All the tests used, as has been pointed out, were submitted to careful preliminary investigations, and these controls showed that Ehrlich's aldehyde, the urobilin, Rouche's, and the lipase content tests could be relied upon; therefore deductions may be based upon the results obtained from these tests.

#### CONCLUSIONS.

If the series of cases investigated be now examined, it will be seen that out of a total of 56\* cases, where arsenical preparations had been given, in 52 the chemical reactions indicated that the liver tissues at the time the tests were made were functioning normally. Since the derangement of liver function, if any, may arise during the administration of arsenical, or at varying periods afterwards, it is of importance that any series of tests be made at different times. This has been done, and it will be noted that the range extends from four years and eight months through gradually shortening intervals down to a period when the tests were made while the patient was actually under arsenical treatment. These investigations go to show that does not cause either immediate or late damage to hepatic tissue except in a small proportion of cases. It should not be inferred that the proportion of jaundice met with in the clinic is 5 out of 56. Examples of jaundice are rare, and we were fortunate in obtaining these while the investigations were being carried out.

There is now an extensive literature on the subject of what may be called arsenical jaundice. So striking and suggestive a phenomenon as jaundice could not escape notice, but it is open to question whether the arsenical preparations used should be held entirely or generally responsible for the condition observed. Jaundice, and even acute yellow atrophy, were noted in connexion with syphilis long before arsenic was employed in the treatment of this disease. This is very fully dealt with in the admirable report of the Salutarian Committee of the Medical Research Council on the toxic effects following the arsenobenzol preparations. There will be found among other records that of Lasch (1884), who noted 49 cases of jaundice in early syphilis, including one where acute yellow atrophy supervened; that of Wickham Legge of 100 cases of acute yellow atrophy, 8 of which were known to be syphilitic; that of Parkes Weber (1909) recording acute yellow atrophy in a case of recent syphilis; and others similar. There is thus abundant evidence that every degree of jaundice, and even acute yellow atrophy, may occur in syphilis as an accident of this disease, and therefore may be in no way connected with the use of an arsenical preparation.

In view of these facts many hold that the jaundice observed in syphilis, whether following salutarian administrations or otherwise, should be attributed to a special effect of syphilis on the liver. There are, however, two facts of general acceptance which appear to challenge the complete acceptance of such a hypothesis. The first is the well known observation that the administration of arsenic for various conditions in individuals free from any syphilitic taint may be followed by jaundice; the second is concerned with the occurrence of groups of cases of jaundice or acute yellow atrophy in seeming epidemic form among patients being treated for syphilis with arsenical compounds. In the latter cases the suggestion has been made that some additional infection is present and that persons suffering from syphilis are especially liable to infection of this kind. But even allowing full value to these observations, it can nevertheless be maintained from the evidence we have given that the arsenical substances may be safely employed in full doses without any considerable chance of causing temporary or permanent damage to the liver tissues. In this connexion four cases may be cited.

The first, No. 1508 in our series, a male aged 54, with old syphilis, was observed in one case where liver functions were investigated (No. 1508) no arsenic was given.

It is easy to see that had this man been treated with arsenic the condition discovered would improperly have been attributed to the drug used. Further, if salutarian is as expected that where hepatic disease is already present the administration of the drug would produce some pronounced harmful effect. The following cases contradict such an assumption. No. 859, a female, aged 54, came to the hospital in 1918 with an enlarged and irregular liver diagnosed as syphilitic. She gave a history of several attacks of jaundice, there were scars about the region of the knee, and the Wassermann reaction was positive. This woman received 9 grams of narsobenzol in ten injections, following which the liver ceased to be palpable, and she made progressive improvement. Chemical investigations of the hepatic functions two years and two months after treatment had been commenced gave positive results (see Table I), although the patient's general condition still remained good. No. 1515 is an example of a similar kind. This patient, a female, aged 55 years, was admitted to a medical ward with the diagnosis of syphilis of the liver; the Wassermann reaction was positive and the liver was considerably enlarged. She received 5.50 grams of narsobenzol, and six months after the first injection the liver could no longer be felt. The third case is an example of jaundice during the early secondary period. The patient, a female aged 20 years, presented herself with marked jaundice and secondary syphilis. In spite of this she was given a first injection of 0.5 gram of narsobenzol, following which the temperature rose to 102.2, the liver again became enlarged and tender. A fortnight later a further injection of 0.5 gram was given. The jaundice had by now almost entirely disappeared, and from this time the patient made satisfactory progress.

While admitting that jaundice may result from the inspection of any form of arsenic and apart from syphilis, and also that there is some evidence of the occurrence of epidemic jaundice among patients being treated for syphilis—which may point to some additional unknown factor—we are nevertheless of the opinion that, in the type of jaundice met with in the clinic where our observations have been made, the condition should rather be attributed to the disease than to the remedy used. Thus we have been unable to confirm the findings of others that a disturbance of liver function is common after arsenical administration; indeed, our observations lead us to take a contrary view. Further, it has been noted by us that in a number of cases where jaundice supervened during treatment, although the results of treatment might appear entirely satisfactory, after an interval the Wassermann reaction, which may have been, and usually was, negative, again became positive, indicating that sterilization had not been complete. It may reasonably be supposed that in these cases certain spirochaetes had escaped and had assumed a special activity in the liver substance, first producing jaundice and later the positive Wassermann reaction. It would appear certain that the incidence of jaundice among those suffering from syphilis is no higher than formerly. This may, however, be explained on the assumption that in consequence of the rapid destruction of the infecting parasites by the specific remedy, close natural processes of protection which would normally be called into being are not elaborated, and thus any escaping micro-organisms and the tissues invade in an unprotected state. This would account for the phenomenon noted—that is, jaundice. It is interesting to recall that in the early days of the use of "606" the remedy was blamed for the lesions of central nerves then not infrequently observed, but that later it was shown that these effects were the result of the disease, not of the remedy employed to treat it. These investigations were undertaken with an entirely open mind. The object was to determine whether the

present themselves at different points and under the influence of the injury, and under the different mechanical conditions obtaining respectively in the upper and lower parts. An interesting account is given of the mode of development of the level bony surfaces destined to bear the pressure parallel to the axis of the shaft. The manner in which the bone is deposited and the definitive structure of the pressure surfaces are well described and illustrated. The influence of the several mechanical forces—pressure, friction, and tension—in producing the complicated structure of the transverse fibrous plate, with its laminous deposits, fragments of osseous tissue, collection of calcareous debris, and variously directed fibrous areas, are also fully discussed. The formation of the articular cavity has been variously explained by different theories as resulting from haemorrhage, or from softening of the tissues consequent on hyaline degeneration and atrophy of the vessels. Mitterstiller ascribes it to the relative movement between adjacent tissue strata, and there is evidence in support of this view. The paper is illustrated by a number of excellent microphotographs, and contains a detailed account of the literature of the subject.

#### INTERNATIONAL CONGRESS OF OPHTHALMOLOGY.

It had been proposed to hold an international congress of ophthalmology in London in 1925, but it has been decided to postpone it. We are informed that the committee of British ophthalmologists appointed to organize the congress with regret that it is unable to do so in accordance with the conditions under which the British invitation was accepted by the Washington Ophthalmological Congress in 1921, when it was decided that the next congress should be entirely international and that German should be one of the official languages. The committee has since been informed that the Société Française d'Ophthalmologie, the Société d'Ophthalmologie de Paris, and the Société Belge d'Ophthalmologie have passed resolutions to the effect that they feel themselves unable to participate in a congress if Germans are invited. The committee is of opinion that to proceed with the congress in these circumstances would be to perpetuate a schism in the ranks of ophthalmology, and would militate permanently against the progress of the science which all desire to promote. The committee has, therefore, reluctantly decided to postpone the congress.

#### THE CENTENARY OF THE "LANCET."

A dinner in celebration of the completion of the hundredth year of the *Lancet* will be held in London on Wednesday, November 28th, 1923. Sir Donald MacAlister, president of the General Medical Council, will take the chair, supported by the President of the Royal Society, the President of the Royal College of Physicians of London, the President of the Royal College of Surgeons of England, the Chief Medical Officer of the Ministry of Health, the President of the Royal Society of Medicine, and the President of the Medical Society of London. Dr. J. W. H. Macleod and Mr. H. D. Gillies (7, Portland Place, London), are acting as honorary secretaries to the Dinner Committee.

#### THE PRICE OF INSULIN.

The Ministry of Health announces through the secretary of the Insulin Committee, Dr. G. F. McCleary, that the retail price of insulin has been reduced. Until a few weeks ago, the Ministry states, the American retail price, formerly higher, was 2d. per unit, or 1s. 6d. per unit in an alternative strength. The corre-

responding price in the United States is reduced to approximately 2d. per unit. Hospitals have, in fact, had the advantage of this reduction already during the present week. They are allowed a trade discount of 15 per cent. on the retail price, and will thus now pay about 1½d. per unit. The main reason for the difference of price in the United States is that manufacture there began, under the guidance of the workers in Toronto University, some months earlier than was possible here. But as laboratory processes are progressively converted into large-scale manufacture the price goes down, and the decline in this country, in spite of certain handicaps, has been greater proportionately than in the United States. The British Drug Houses, Ltd., inform us that the reduced price became effective on July 12th, and that supplies are sufficient to meet all demands.

#### PRESERVATIVES AND DYES IN FOOD.

The Minister of Health has appointed a committee to inquire into the use of preservatives and colouring matters in food and to report (1) whether the use of such materials or any of them for the preservation and colouring of food is injurious to health, and, if so, in what quantities does their use become injurious; (2) whether it should be required that the presence of such materials and the quantities present in food offered or exposed for sale should be declared. The committee is constituted as follows: Sir H. G. Monro, K.C.B. (chairman), Professor W. E. Dixon, O.B.E., M.D., F.R.S., Sir A. D. Hall, K.C.B., LL.D., F.R.S., Dr. J. M. Hamill, O.B.E., M.D., D.Sc., Mr. O. Helmer, F.I.C., Professor F. G. Hopkins, F.R.C.P., F.R.S., Dr. G. R. Leighton, O.B.E., M.D., Dr. A. P. Luff, C.B.E., M.D., F.R.C.P., Dr. C. Porter, M.D., B.Sc., and Mr. G. Stubbs, C.B.E., F.I.C. The secretary of the committee is Mr. A. M. Legge, of the Ministry of Health, Whitehall, S.W., to whom all communications should be addressed.

Mr. Godfrey Locker-Lampson, Under Secretary for Home Affairs, Sir Arthur Stanley, Lieut.-Colonel Fremantle, Lord Dawson of Penn, Sir Thomas Horder, and Sir Edward Marshall-Hall, on behalf of the British Empire Cancer Campaign, met, at the House of Commons on July 10th, representatives of the Royal Society and the Medical Research Council. A discussion took place regarding the scientific side of the campaign, and it was decided to form an Advisory Committee to assist the carrying on of the campaign from a scientific standpoint, if the necessary agreement upon details could be reached.

Red Cross Societies have always esteemed it one of their duties to come to the assistance of the inhabitants of districts which have suffered from such disasters as earthquakes, floods, or great mine explosions. At the instance of Senator Ciralo, president of the Italian Red Cross Society, and with the approval of the Society of Nations, the International Red Cross Committee has proposed to organize such work more thoroughly, and as a first step to prepare an atlas of catastrophes, according to a plan evolved by M. Raoul Montandon, president of the Geographical Society of Geneva. He has prepared a pamphlet on the subject, illustrated by sketch maps, and suggests that a chronological list of catastrophes should be drawn up, giving precise details as to their remoter causes, the regions affected, and the loss of human life and material destruction involved. The assistance of scientific institutions is invited in the preparation of local reports, upon which the International Red Cross Society will be able to found the proposed atlas. Communications should be addressed to the

NINETY-FIRST ANNUAL MEETING

of the

British Medical Association,

PORTSMOUTH, 1923.

OLD PORTSMOUTH AND PORTSEA.

At the end of Highbury Street the old chapel of St. Mary of Close stood from 1320 to the time of Elizabeth. Later another chapel of ease to St. Thomas's was built here and opened in 1839. The church, closed at the beginning of this century, has been razed, and the ground is now laid out as an "open space." Before the fortifications were demolished leading from St. Mary's Road was a narrow way across an iron bridge over part of the old Mill Pond to Portsea. There is now a good road; the visitor should proceed to Portsea before returning to High Street. The old Mill Pond was filled in with the earth from the old walls, and the ground levelled, now forming the Men's Recreation Ground. Just before passing under the railway arch is the entrance to the old Gun Wharf. The old part of the wharf dates from 1662. Here were parked all manner of stores for military and naval use, many old relics were stored, and the Armory was decorated with designs similar to those seen in the Tower of London. The army stores are now at Hilsea, the naval stores at Gosport, and the armory at Camberley. Passing under the railway arch, on the right St. George's Square and Church can be seen. At No. 3 in the square is the house in which Sir Walter Bessant was born on August 14th, 1836. He was educated in the town, and was a regular visitor to his natal town after he ceased to reside therein. He describes the church in his novel, *By Cellia's Arbour*, under the name of "St. Faith's," thus: "Externally it was a great barn of red brick set in a courtyard surrounded by a red brick wall with a roof of red tiles." The church was built in 1753. On the east side of the square is Britain Street. In a house in this street Isambard Brunel was born on April 9th, 1806.

The way to the Dockyard is westwards along Common Harb, the landing place for civilian goods and not reserved for Admiralty stores. It was a wild spot till the shipwrights began to build houses for themselves near the yard in Queen Anne's reign. The governor of the dockyard at that time—Colonel John Gibson—objected to the building as he wanted a clear space all around for the better defence in case of attack. Prince George of Denmark supported the men's appeal, and in memory of his success the shipwrights called the first street Prince George Street, and by that name it has continued to be called. The Harb is not a particularly beautiful place, and the railway to the Harbour Station for the Isle of Wight boats greatly interferes with the view of the harbour. Nor are the logs, the black mud, and the mudlarks things of joy. The Harb, too, is a curious study for those interested in the drink question. Within 200 yards one could count

FIG. 1.—LANDPORT GATE.

fifteen public houses; there are plenty now, and at one time there were more. The only establishment of any note amongst them is "Keppell's Head," an old naval house. Facing us at the end of the Harb are the main gates of the Royal Dockyard. A tablet in the wall by the side tells us they were finished in 1709. Before their erection the entrance to the yard was at Bonfire Corner, about a quarter of a mile further along the road. Still further on, at the end of Unicorn Road, is the other entrance to the yard. Unicorn Gate, together with Lion Gate, were once part of the old Portsea fortifications. These gateways were erected in 1778, the Lion Gate at the eastern end of Queen Street, the Unicorn Gate at the end of North Street. After the dismantling of the fortifications the Unicorn Gate was re-erected to make a new entrance to the yard. The Lion Gate was turned through a right angle and used quite near its old situation as the entrance to Anglesey Barracks. These barracks, together with some old convict quarters, have been cleared away and the ground absorbed by the present Naval Barracks. The stonework of the old Lion Gate has been preserved, and it is hoped that the near future will see the gate re-erected in some prominent position in the borough. At the Bonfire Corner end of Queen Street is the end of Cross Street; at the end of Cross Street is Orange Street, and not far from here St. John's Church, formerly known as St. John's Chapel; it was built on Portsmouth Common in 1767 in the Venetian style, and, like St. George's, is a large red brick building. Orange Street has associations with Whitefield. He as well as both Wesley's visited Portsmouth several times. In Orange Street as a result of Whitefield's visits "The Tabernacle" was opened in 1754. A little later in Daniel Street, parallel to Cross Street, the first Methodist church in Portsmouth was established. Leaving the dockyard for a visit on another occasion, we will return to where we left old Portsmouth and end our way to High Street. In 1860 a Royal Commission came to the conclusion that fortifications like those of Portsmouth were obsolete. A few years later the ramparts were demolished, the Mill Pond filled in, and the present Recreation Grounds formed. Of the old Portsmouth gateways the Landport or Town Gate alone occupies its original position. It now forms the entrance to the Men's Recreation Ground. The old Landport roadway has been diverted; the new road is in a line with High Street. The stonework of the gate-dates from 1760. It was at this gate that the lieutenant-governor delivered the keys of the garrison to Royal visitors. An interesting description of the old spot is contained in Bessant novel, *By Cellia's Arbour*; it is also the scene of an episode in Meredith's *Evans Harrington*.

methods of treatment employed were liable to cause injury to the hepatic tissue. This we believe not to be the case, and the evidence upon which this belief is based is given above.

## INSULIN IN ALCOHOLIC SOLUTION BY THE MOUTH.

BY

G. A. HARRISON, B.A., M.B., B.Ch.CANTAB.,\*  
 CHEMICAL PATHOLOGIST, KING'S COLLEGE HOSPITAL, LONDON.

In view of L. B. Winter's experiments on rabbits,<sup>1</sup> tests were made on a "pedigree" patient to see if it was a practicable therapeutic measure to administer insulin in alcoholic solution by mouth to man. Winter used very large doses of insulin. The present results in no way contradict Winter's findings—in fact, one experiment definitely supports his work; but they suggest that oral administration in alcohol would be so uncertain and so expensive as to be of little or no therapeutic value in diabetes mellitus in man.

The patient selected was a woman of 31 who has been treated with insulin and rigid dieting since April, 1923. Since September 26th her daily food intake has been 20 grams carbohydrate, 60 grams protein, and 120 grams fat, the carbohydrate being restricted to green vegetables. This amounted to 28 calories per kilo of body weight. With this diet she has taken 20 units insulin each morning and 15 units each evening.

The analyses are given in the table, and the single positive finding, one of the three negative experiments, and the control test with subcutaneous insulin in the chart. The same batch of insulin—namely, A.B. 239—was used throughout. For oral administration the insulin was removed from the phial by a sterilized syringe in the ordinary way and mixed with the requisite amount of alcohol and distilled water, the vessel being finally washed out with more of the diluted alcohol, which was also swallowed.

| Glycosuria, after the meals ... ..                                                                            | Nil                            | Nil                            | Trace                                  | Trace                          | Marked                          | Marked                                |

Having shown in Experiment 1 that the particular of insulin (A.B. 239) was potent when given subcutaneous and that the dose of 20 units was causing the usual blood sugar for this particular patient, 30 units were by mouth on an empty stomach in 17½ c.cm. 20 per cent. alcohol (1½ c.cm. insulin solution, plus 6 c.cm. 25 per cent. alcohol, plus 10 c.cm. 20 per cent. alcohol). The result was decidedly hopeful (Experiment 2). Next day it was that 17½ c.cm. of 20 per cent. alcohol alone were given (Experiment 3), there being the typical d

rise in blood sugar lasting over three hours even a small meal as 5 grams carbohydrate, 12½ grams protein, and 29½ grams fat. Three days later 40 units in 20 per cent. alcohol were given by mouth on an empty stomach (Experiment 4) without any apparent effect ever. It was thought that the alcoholic solution had been rapidly through the pylorus. In the next experiment, therefore, the 40 units were given after food—five minutes after a starch-free bran biscuit and half an ounce of butter again with negative result (Experiment 5). Lastly, the effect of increasing the strength of the alcohol was tested (Experiment 6); 40 units in 20 c.cm. 40 per cent. alcohol were given, again without effect on the blood sugar (after breakfast). To make sure again that the insulin used was potent, 20 units were given subcutaneously the same day immediately before lunch, with the fall in blood sugar.

From these tests it will be seen that, with one exception (Experiment 2), a dose of insulin by mouth that required subcutaneously is valueless. Even when it were possible to supply insulin in alcoholic solution

half its present price it would still be more expensive to give it orally. But to my mind much more serious than expense is the uncertainty of the oral method of administration. The very fact that a single positive result was obtained shows the possible danger of the method. We have no control over the pyloric sphincter. Also it is conceivable that there might be danger for those with achlorhydria (and it is to be remembered that 4 per cent. of healthy individuals are estimated to have achlorhydria) in that pepsin would not be activated, and in that an oral dose, if calculated from a series of experiments on other patients as being a certain multiple of the subcutaneous dose, might be an overdose for the achlorhydric. Moreover, if the insulin were given with food it is possible that variations in the articles of diet (in spite of keeping the intake of carbohydrate, protein, and fat constant) might influence the proportion of insulin absorbed or destroyed by pepsin.

The experiments are admittedly few in number and confined to one patient. This patient is an expert at diet calculations, however, and has submitted to a large number of blood sugar curves for previous experimental work. She has for several weeks given herself 35 units of insulin daily, and her fasting blood sugar, tested frequently, has remained steady within narrow limits. She, of course, stayed in the laboratory for these special experiments, eating her food off the laboratory bench. The results are recorded in the hope that other workers who have done similar experiments will publish their findings, and so prevent the raising of false hopes in the minds of those suffering from diabetes mellitus.

## A CASE OF MALARIA ARISING IN THIS COUNTRY.

BY

NEVILLE M. GOODMAN, B.A., M.R.C.S., L.R.C.P.

ALTHOUGH nearly five hundred cases of locally contracted malaria have been discovered in England since 1917, the vast majority of them can be traced to infection from cases returned from abroad. Indeed, it is probable that malaria is no longer endemic anywhere in England save in the isles of Sheppey and Grain on the south bank of the Thames estuary. The chief interest of the following case is that it suggests the possibility of another endemic focus in the Essex marshes on the opposite bank.

K., a girl aged 12, was admitted to the London Hospital on September 10th, 1923, with the following history:

A fortnight previously she had returned to her home in the East End from a Girl Guides Camp at Pitsea, Essex. Ten days later (that is, five days before admission) she had had a "shivering attack" followed by headache and "stiff neck"; the attack was repeated two days later. She felt quite well and said there was nothing wrong with her. Her bowels had been constipated since the onset and she had vomited once after the first attack. She had had no previous illness.

Her father, while at Gaza in September, 1917, was ill for three days with "sandfly fever"; he was cured by pills and did not leave the battery lines. In September, 1918, he had a similar attack in France; again he was cured by opium and quinine pills without going into hospital. He has had no attacks since and has been in perfect health. The mother is healthy and has had no shivering attacks; one other child, aged 9 years, is healthy.

The patient was a pale, intelligent child in no pain or distress. Temperature 105°, pulse 140, respirations 30. The tongue was furred; the heart and lungs were clear; spleen enlarged 2½ finger-breadths below the costal margin, uniform and rather hard.

*First Day.*—Rigor at 4 p.m.—four stages: (1) coldness of the feet spreading to the body; (2) trembling of shoulders and legs; (3) short sleep; (4) awoke feeling hot and sweating.

*Second Day.*—Rigor 5.30 p.m.

*Third Day.*—Rigor 2 p.m.; parasites (benign tertian) found in the blood.

Treatment by quinine was started. There were no more rigors, and the temperature remained normal. On discharge ten days later the spleen was not palpable.

The length of time (five years) since the father's last attack—if, indeed, he ever had malaria—and the absence of the anopheles mosquito from the East End district in which the patient lived eliminate the father as the source of infection. No history can be obtained of any lodger,

relative, or neighbour ever having suffered from malaria, and everything points to the child's infection having been acquired while in camp. The children slept there in three barns situated in a lonely spot in the marshes south of Pitsea. The nearest habitation, the farm to which the barns belonged, was about half a mile away and was itself some three miles from Pitsea village. Inquiries revealed no recent cases of malaria and no returned soldiers were living in the neighbourhood. The farmer stated that in his youth "everyone" on the marsh had "ague," and he himself had had two attacks, one as a boy and one as a young man, some thirty years ago. He gave a vivid description of a typical attack of malaria. On examination his blood showed no parasites.

As late as October 30th mosquitos were plentiful in the neighbourhood and three were caught inside the barns where the children slept; they proved to be *Culex pipiens*. Pitsea, however, is given as a locality for *Anopheles maculipennis* by the authorities of the British Museum (Natural History).

I am indebted to Dr. Robert Hutchison for permission to publish this case.

## SPONTANEOUS RUPTURE OF THE LOWER UTERINE SEGMENT.

BY

D. S. PRACY, F.R.C.S. EDIN.,  
ATHERSTONE, WARWICKSHIRE.

SPONTANEOUS rupture of the lower uterine segment must be a very rare occurrence, and perhaps on this account the notes of the following case may be of interest.

I was asked to see a patient, aged 30 years, at 5.45 p.m., on account of abdominal pains which had commenced an hour earlier. She was then in the thirty-sixth or thirty-seventh week of her first pregnancy. The pains had the character of first-stage labour pains. External examination showed the child to be lying in the left occipito-anterior position. No vaginal examination was made as at the routine examination two or three weeks before no abnormality had been discovered. At 6 p.m. the pains became much more severe and I commenced the administration of chloroform through Junker's inhaler. At 6.15 the patient, although under the influence of chloroform, made a violent expulsive effort and the child was born. The infant weighed only 5 lb. and its head was very soft. Immediately following the birth of the child a large haemorrhage occurred. The patient was turned on to her back and the fundus of the uterus grasped; this was found to be well contracted. A hand was then passed into the vagina, and a laceration was found which admitted the whole hand and which extended through the cervix and lower uterine segment into the left broad ligament. The placenta was rapidly removed from the cavity of the uterus and the cervix drawn down to the vulval orifice. Two volsellas were then placed side by side at right angles to the cervical axis so as to take a broad grip of the walls of the tear and the cervix was then allowed to ascend to its normal position. The volsellas thus made a partial torsion of the line of laceration and controlled the bleeding. There was no damage to the vaginal walls or to the perineum. The usual methods to combat the shock were then adopted. Dr. Thomas Wilson saw the patient in consultation at 8.30 p.m., and it was decided to have the volsellas *in situ* for forty-eight hours, and unless the haemorrhage recurred to carry out no further surgical procedure. The tear healed soundly and the patient made an uninterrupted recovery, but a certain amount of tenderness has persisted low down in the left iliac fossa ever since.

Seven months later the patient found herself pregnant again. No complications arose during the pregnancy, but during the thirty-fifth week it was found that the foetus was lying in the left sacro-anterior position. As spontaneous version did not occur, at the commencement of the thirty-ninth week external version was done under a general anaesthetic. The resulting position was right occipito-anterior. The child was born two days later; it weighed 7 lb. Except for a slight opening up of the cervical laceration the labour was without complications.

The cause of the extensive laceration at the first labour is obscure. No complications had arisen during the pregnancy, and as the urine had remained free from albumin it would appear that toxæmic causes need not be considered. The tear extended so far upwards that it was impossible to

inch, a chisel is inserted, and the projecting portion of the os calcis is divided, elevated, and removed. A tube is inserted, which is removed in two or three days; the stitches are removed in a week, and the foot put up in plaster-of-

Paris for two months.

Even in severe cases of talipes equino-varus the foot can be completely rectified by removal of half an inch of the

os calcis. If when this amount of bone has been removed the outer border of the foot should still not be straight,

more of the os calcis should be removed, even up to one inch.

Should the outer border of the foot still not be straight, a

portion of the cuboid should be removed. It is never

necessary, in my opinion, to remove the whole of the cuboid.

I have never seen a case of talipes equino-varus, even

in an adult, where the outer border of the foot could not

be made straight and the deformity entirely remedied by

removal of the whole of the great process of the os calcis,

together with a portion only of the cuboid, provided that all

the right structures on the inner part of the foot had been

previously divided.

*Growth of the Outer Wall of the Os Calcis.*

This deformity results in an obliquity of the upper surface

of the os calcis, and is due to an increase of the vertical

measurement of the outer surface. This condition is in some

cases associated with an ankylosis between the astragals

and the sustentaculum tali. It is only met with in the most

severe cases of long-standing congenital equino-varus, and

is the direct result of long continuance of the foot in the

deformed position. In such cases the os calcis undergoes

this tilting on an antero-posterior axis, and to rectify

it is necessary to open the astragalo-calcaneo-

joint, and to remove a portion of the upper and outer sur-

face of the os calcis. It may be necessary to divide the

anklyosis which may have taken place between the astragals

and the sustentaculum tali. When this ankylosis is divided,

and an appropriate piece of the upper part of the outer

surface has been removed, the os calcis can then be rotated

outwards and placed in its normal vertical position.

*Disease.*

This deformity, an overgrowth of the tubercles on the

under surface of the os calcis, leads to considerable difficulty

in walking. These tubercles give attachment to the abductor

minimi digiti and flexor brevis digitorum muscles. They

may be so enlarged as to project as sharp points half an

inch long. They may cause so much pain and discomfort in

walking that no amount of padding in the boots, or wearing

of thick socks, will relieve the pain. In such cases x rays

must be resorted to, and if the spicules are found, they should

be removed by operation. An incision should be made on

the outer aspect of the heel, one and half inches forward

along the outer border of the foot, and extending backwards

round the posterior part of the os calcis. By this incision

the whole of the posterior half of the inferior surface of

the os calcis can be exposed without damaging any vessel

or any nerve. The tubercles can be removed, and can be

chipped away at their attachment. Unless these tubercles

are thoroughly removed, and the bone left flat, recurrence

of the disability is not prevented.

### Overgrowth of the Epiphysis.

This deformity, overgrowth of the posterior part of the

os calcis, is much more common than is usually thought. It

is becoming increasingly frequent owing to the violent

athletic exercises which are at present indulged in at an

early age. It is usually due to hypertrophy of the epiphyseal

cartilage. The tendo Achillis, it will be remembered, is

inserted into this epiphyseal cartilage, and constant violent

contraction of the tendo Achillis stimulates and causes an

overgrowth of cartilaginous bone at this part.

The osteophytic outgrowth may be so prominent that not

only is it difficult to make the patient's boots fit comfort-

ably, but as the result of excessive pressure and friction a

enlarged, and tender after a spell of exercises, even when

that exercise has been of short duration. In one case which

I remember the patient was laid up for ten days with acute

pain and inflammation in this bursa every time she took a

step.

The treatment should be directed towards getting a

perfect functional result—that is, one in which movement

in all directions was just as free and strong as in the case

of the unaffected limb. By suitable measures this could be

achieved.

*Treatment.*

The treatment should be directed towards getting a

perfect functional result—that is, one in which movement

in all directions was just as free and strong as in the case

of the unaffected limb. By suitable measures this could be

achieved.

When this epiphyseal enlargement causes such an amount

of inconvenience as to materially interfere with the comfort

and destroy the post-tumour.

These sinuses should not be scraped—scraping only removes

the os calcis should be laid open and removed by chisel.

at the bottom of the cavity, the projecting necrosed portion

of the sinus persists and a projecting mass of bare bone is found

is thus put at rest the sinus may continue for years. Should

through which the sinus can be dressed. Unless the foot

put up in plaster-of-Paris, with a window round the heel,

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

putate, and a sinus or necrosis results, the foot should be

t of the uterus at least may not have been or full development. The juvenile form of cervix so often seen in association with acute ante flexion or primary retroversion small uteri is fairly common, and it may be that this patient had such a cervix. The lateral situation and longitudinal extension of the laceration appear to favour this explanation of its origin, and so does the fact that in the

patient always had severe abdominal pain before the onset of each period and occasionally passed small clots. Since the birth of the first child pain has been practically absent and the loss has been much more profuse.

I am indebted to Dr. Thomas Wilson for much helpful advice, both in the care of the patient and in the preparation of this note.

### PROCEEDINGS OF SECTIONS AT THE ANNUAL MEETING, 1923.

#### SECTION OF ORTHOPAEDICS.

H. OPENSILAW, C.B., C.M.G., M.S., F.R.C.S., President.

#### DISCUSSION ON

#### THE OPERATIVE TREATMENT OF OSTEO-ARTHRITIS.

##### OPENING PAPER

BY

REGINALD CHEYNE ELSLIE, O.B.E., M.S.,  
F.R.C.S.,

Orthopaedic Surgeon, St. Bartholomew's Hospital.

ARTHRITIS DEFORMANS is somewhat difficult of definition; undoubtedly embraces cases due to a variety of causes. McCrae attempts to define it as a group of cases of arthritis which have as prominent features a tendency to chronicity and to the production of more or less permanent changes in the joints or structures about the joints, those forms of arthritis with a definite known aetiology (for example, gonorrhoeal arthritis) being excluded. This would make this difference—that it is perhaps better in the practical point of view to retain those cases included in the latter part of this definition, if they are chronic and deforming. When considering cases of arthritis from the surgical point of view, one is bound to found one's views of treatment largely on the practical result that arthritis has produced and not entirely upon the etiological factors. McCrae says it is important to remember that arthritis is always secondary to a process elsewhere; the joint condition is not primary. In this he has perhaps paid insufficient attention to the occurrence of arthritis in a deformed joint—for example, the frequent occurrence of arthritis in coxa vara and coxa plana, in genu valgum, and in joints which have been damaged by intra-articular fractures, or whose alignment has been interfered with by a fracture farther away from the joint.

It is difficult to determine how many diseases are really included under arthritis deformans. It is quite certain that "in all chronic joint changes the same cause may produce varied results and the same results may come from different causes." There appear to be many causative elements, of which we may class as the most important:

1. Infection of the joint with a micro-organism of low virulence.
2. Toxaemia, possibly from a bacterial poison, possibly from a chemical poison.
3. Trauma, including not only direct damage to the joint structures by injury, but also the reaction to an abnormal strain and an interference with the proper fit of the joint surfaces, due to old-standing injury or deformity.

The physiology of joints is not yet very well understood. The secretion of synovial fluid is still somewhat of a mystery; there are no glands for this secretion, and it is

formed apparently by the cells lining the synovial membrane, presumably through some form of proliferation and mucoid change. It is believed that the cartilage covering the bone surface is in a constant state of cell growth towards the articular surface. The bone underlying it and around the margins of a joint we know to have potentialities of growth and alteration throughout life. The whole of the interior structures of a joint must thus be looked upon as possessing potentiality for growth, which shows itself in the reaction to any of the above-mentioned causes of arthritis.

Changes in the cartilage in the shape either of thickening, or of erosion and ulceration, changes in the synovial membrane in the shape of proliferation or of fibrosis and thickening, and changes in the bone in the shape of overgrowth at the joint margins, may all occur in a chronic arthritis due to any of the many different causes. In addition there is a far greater potentiality for the formation of new tissue in joint structures than is commonly realized. We know that cartilage may not only thicken, but may also extend over osteophytes around the joint margin, that new masses of cartilage may develop in or under the synovial membrane, and that small portions of cartilage or synovial membrane flaked off and lying in the joint cavity may undergo growth into cartilaginous loose bodies, and bones may develop in their interior. We must discount the actual nature of the pathological changes in every case when we try to estimate the causation. It is quite clear that these many changes are of the nature of a reaction of the joint structures to an injury, or to a bacterial or chemical poison, and are none of them specifically due to any one of these causes.

The classification into clinical types—that is, into those mainly characterized by periartritic changes, and others of the atrophic and hypertrophic types—is useful, but is not of any special service from the surgical point of view.

Operative treatment has a very definite place in the treatment of arthritis deformans, but in the main it concerns itself with the removal of mechanical causes and with the treatment of particular functional disabilities. Operative treatment must always take a secondary place to a careful medical investigation and treatment of any primary cause. The first steps in treatment should be:

1. The determination, as far as is possible, of the existence of any specific infection or toxæmia.
2. The determination of the existence of any mechanical cause.
3. The treatment of an infection or toxæmia, if it has been found to exist.
4. The treatment of the more acute periods of inflammation by rest.

The operative procedures which may be useful in arthritis deformans may be classified under the following heads:

1. Operations to correct pre-existing deformities—for example, osteotomy to secure abduction of the hip in coxa vara, osteotomy of the femur for genu valgum, genu varum and genu recurvatum.
2. Operations to remove an intra-articular cause of the arthritis—for example, removal of a permanently displaced internal semilunar cartilage or of a cartilage which is constantly being displaced, and which by its mechanical effect is producing secondary arthritic changes in the knee-joint; removal of a loose body or of a foreign body from the

Hence, the treatment of an old case by operation, a resection, or where no resection was not complete, it is at a case in which the disease is so severe as to be severely impaired.

*Remarks.*

[illegible]

The fracture occurred almost entirely in children.

It was the commonest fracture affecting the lower end of the humerus. It could be caused by a quite trivial accident. It was usually described as a separation of the lower ends of the humerus, but this was a great rarity, many of these cases could not be reduced by manipulation, and a poor functional result followed.

They could, however, be reduced accurately by operative treatment should therefore be employed more often than at present.

Roeth showed radiograms of eight cases, taken before after operation.

THE TREATMENT OF CONGENITAL TALIPES  
EQUINO-VARUS.  
BY  
NAVUGHTON DUNN, M.A., M.B., Ch.B. ABERD.,  
Consulting Orthopaedic Surgeon, Ministry of Pensions,  
West Midlands Region.

In this case the fore-part of the foot is adducted mid-tarsal joint, but there is no inversion of the os

tion to this, however, and to suggest that the differential diagnosis is not important, but because the treatment adopted is essentially the same.

deformities and disabilities which sometimes result from treatment.

My belief is that any effective management program must be based on the concept of the "total organization". The total organization is that organization in which the individual, the group, and the organization are all interrelated and interdependent. The total organization is that organization in which the individual, the group, and the organization are all interrelated and interdependent. The total organization is that organization in which the individual, the group, and the organization are all interrelated and interdependent.

[illegible]

*Duration of Treatment.* Perhaps before discussing the line of treatment to adopt

[illegible]

root—and the tendency to a more rational and useful treatment of congenital club-foot. It is perhaps a less serious deformity. A fixed valgus has been established, but the goal at which we should aim is the normal foot. It is for this reason, as we have to give our arguments to the possibility of relapse, that consistent supervision is necessary for several years to ensure the best result.

**TREATMENT.**

The routine consists of correction of the adduction, correction of the inversion, followed later by the correction of the equinus position of the foot. This routine is obvious and generally accepted. Further results more often, I am sure, from a lack of appreciation of the severity of the malpositioning which an infant's foot will sustain and which is necessary to obtain complete over-correction of the deformities.

In the correction of adduction it is important that the foot should be abducted at the mid-tarsal joint, and that the correction of the inversion should take place mainly at the subtarsal joint. If the corrective force be transmitted to the astragalus, it will result in a forcible rotation of the bone in its relation to the ankle-joint. An apparent correction when this has occurred is always followed by relapse, however, as the rotation of the bone is continued. I feel sure that lack of correction of the point has been responsible for many of the failures of this treatment.

In our correction it is therefore essential that the astragalus should be maintained on the outer surface of the foot pressure be maintained on the fixed point. This is assured by the astragalus, equal to that used to correct the neck of the astragals, equal to that used to correct the adduction and inversion deformities. Clinically we know that we have a true correction of the deformity if a hollow is present in front of the external malleolus, the heel will be

depression in front of the external meatus with more apparent when the equinus deformity also has been

knee; or the removal of a ridge or irregularity left by a fracture.

3. Operations for an acute condition of arthritis—for example, by an incision of the joint, or by puncture of the joint and washing out of the cavity either with an antiseptic or with normal saline solution, or with ether.

4. Operations designed to improve the functional utility of the joint, or to enable the joint or limb to be used without pain, the pain being due to a mechanical cause and not to an actual inflammation. Operations coming under this heading will include (a) the removal of osteophytes, either because they are blocking the movement of the joint, or because their presence is producing pain on certain movements; (b) excision of the joint, or arthroplasty carried out with the intention of securing a functionally good mobile joint; (c) excision or arthrodesis, carried out with the intention of securing bony ankylosis of the joint in order to improve the functional use of the limb or to do away with pain occurring in a joint in which there is a small remaining range of movement; (d) operations carried out in order to alter the position of a fixed joint, so as to improve the functional utility of the limb.

### 1. Operations to Correct Pre-existing Deformities.

There is no doubt that the abnormal strain upon the joint in coxa vara, genu valgum, etc., is an important cause in the production of a localized arthritis deformans of the affected joint. It is in a sense too late to correct the deformity if the osteo-arthritis has arisen, nevertheless this procedure is often necessary, either simply in order to alter the strain upon the joint and so diminish the progress of the osteo-arthritic changes, or because an appliance is necessary which cannot be fitted in an adequate manner to the deformed joint. The operations required are the standard osteotomies of surgery, such as transtrochanteric osteotomy and Macewen's osteotomy of the femur. They require no further mention.

### 2. Operation for the Removal of a Semilunar Cartilage.

Removal of a semilunar cartilage or of a loose body, which is producing osteo-arthritic changes, would seem to be a common-sense procedure, nevertheless such removal of a mechanical cause is too often neglected. I have removed a semilunar cartilage from an osteo-arthritic knee in which the cartilage had been damaged over twenty years before and had been displaced at frequent intervals over this period of time. The operation stopped the progress of the osteo-arthritic changes and improved the function of the knee very greatly indeed.

### 3. Operations for an Acute Condition of Arthritis.

There is much doubt about the value of such procedures as incision and washing out of the joint. My personal experience of them is not great, and I have little faith in the utility of washing out a joint, except in occasional cases in which a chronic effusion of considerable size fails to diminish as the result of complete rest by splinting. The efficacy of this procedure must necessarily depend largely upon the nature of the cause. It can hardly be expected to be of any value in cases other than those of definite infection of the joint.

### 4. Operations Designed to Improve the Functional Utility of the Joint.

(a) *Removal of Osteophytes.*—This operation may be useful in any of the joints of the body, when an osteophyte has been ascertained to be blocking movement or producing pain. When carried out for such a purpose it is very essential to define exactly the position of the osteophyte: this is best done by means of stereoscopic x-ray photographs. The removal should then be carried out with as little exposure of the joint as possible. In some cases a wide exposure of the joint and a general removal of all osteophytes is a useful operation. It is most often applicable to the hip- and knee-joints. In the hip-joint I prefer to carry out such a proceeding through a posterior (Kocher) incision, lifting the muscles off the great trochanter and opening the capsule above and behind. The head of the

femur can then be completely dislocated posteriorly and rotated in different directions whilst it is trimmed up round all its margins. If the cartilage remaining on the surface of the head and lying in contact with the acetabulum is intact, the femur can then be replaced in its socket and the capsule and muscles sutured. The limb should be kept on a heavy weight extension (20 or 25 lb.) for a period of six weeks, and movement then commenced. It is better to deal only with the femoral surface, unless some evident large osteophyte on the acetabular margin requires removal for mechanical reasons. The cut bone on the femoral neck may be rubbed with a fairly hard wax. This operation is only suitable for subjects up to the age of 45. There is no doubt that this procedure in suitable cases improves the function of the joint for a considerable period and diminishes the pain that is often felt on forced abduction. It is not so severe an operation as might be thought, and it is particularly suitable for those cases of osteo-arthritis of the hip with a large deformed femoral head, seen in young or middle-aged patients, which have probably resulted from a coxa plana arising in early life.

In the knee-joint a similar operation for the general removal of osteophytes is, in my experience, rather less successful. The joint must be approached either by splitting the patella vertically or by a curved longitudinal incision on the inner side, as advocated by Fisher. In the latter case the patella is displaced right over to the outer side of the joint. The margins of the femoral facets and of the patella require trimming up; the tibia is best left alone, except for the removal of any osteophytes which are causing mechanical trouble. If the semilunar cartilages are damaged or ossified, they must be removed at the same time. If the joint surface is found to be much eroded, the result of the operation is not likely to be good. The posterior part of the joint cannot be explored very thoroughly through this incision unless the crucial ligaments are divided, an undesirable proceeding. Fortunately it is seldom that osteophytes in this position require removal. When such are present, they must be approached by separate incisions on the inner or outer side at the back of the knee. Again an extension should be kept on the knee for a period of six weeks before recommencing movement.

(b) *Arthroplasty and Excision.*—Operations designed to reconstruct the joint and leave a mobile and useful joint are decidedly unsuccessful in cases of rheumatoid arthritis. Our first care must be that we leave a joint which is functionally more useful than the deformed joint and at least as useful as an ankylosed joint would be. The second consideration is that the new joint must be free from pain. As a general rule an attempt to make a new joint involves an operation that is more severe than arthrodesis, and where an ankylosed joint would give at least as good use as a mobile joint the latter operation is to be preferred. In the shoulder-joint excision or arthroplasty has so far failed to give useful functional movement. This joint seldom calls for operative interference in arthritis deformans; when it does, it is on account of pain, and an ankylosis of the joint must be considered as the most satisfactory proceeding. Of all the joints the elbow gives the best results by arthroplasty: it is seldom, however, that arthritis deformans affects the function of the elbow to such an extent as to necessitate this operation. Practically, the operation is only indicated in cases in which the elbow is stiffened in a bad position—that is, where the range of movement does not include the right-angled position. Arthroplasty in which the olecranon is left and a flap of fascia inserted is preferable to the old-fashioned excision, which leaves a more mobile, but much weaker joint. In the wrist-joint arthroplasty is not called for. If the radio-ulnar joint has been affected and pronation and supination seriously interfered with, Galilei's operation for removal of a small section of the lower end of the shaft of the ulna is the simplest procedure.

Arthroplasty in the lower limb, more particularly in the hip and knee, has been a far less successful operation than it is in the elbow, the reason being that stability in these joints is essential, and it is therefore necessary to limit the amount of bone excised in order to avoid a flail joint.

corrected. This allows the body of the astragalus to assume its normal relation with the ankle-joint.

The calcaneo-cuboid joint is the main fulcrum in the correction of pure adduction. In correction of the inversion it is essential that counter-pressure should be applied to the outer surface of the neck of the astragalus. It is of the very greatest importance that no strain should be put on the knee-joint during these manipulations.

In practice manipulation may usually be commenced in an infant 3 or 4 weeks old without an anaesthetic. It will be necessary to maintain the position of correction obtained, and to repeat the manipulations once a week until full correction is present. The position of correction obtained must be maintained in the intervals between the manipulations. The method of fixation we adopt is that of strapping and internal splintage:

One layer of lint is placed over the dorsum and lateral borders of the fore-part of the foot. A strip of zinc oxide adhesive strapping 1½ inches wide and 16 inches long conceals the fore-part of the foot. It then projects the lateral borders of the foot from pressure, and traction on the strapping upwards and backwards maintains the position of correction obtained. The foot is held in the corrected position of the upper third of the leg, and maintained there by another strip of adhesive strapping which encircles the limb at this level. A applicable medial splint padded with lint is then applied to the inner surface of the foot and leg, and its position maintained by strapping. This is an aid in maintaining the position of correction until the next manipulation is undertaken.

In a moderate case weekly manipulation for eight to twelve weeks will be necessary before the adduction and inversion are completely corrected. Reasons will sometimes arise where weekly manipulations are not practicable. It is then advisable to give the child an anaesthetic. Two or three manipulations under anaesthesia will usually suffice to produce a complete over-correction of the adduction and inversion, an interval of three weeks intervening between the manipulations.

When the child reaches the age of 3 or 4 months, my experience is that although the correction of the adduction and inversion is complete, the equinus deformity has failed to yield to manipulation. Further efforts to stretch the tendo Achillis and posterior structures should not be persisted in, as these tend to produce an apparent correction of the equinus rather than a true stretching of the tendo Achillis. The strain of manipulation bears after a certain point more on the mid-tarsal joint than on the tendo Achillis. The calcaneo-cuboid joint resists weight-bearing, so that persistent force should not be applied to correct the equinus deformity where simple division or elongation of the tendo Achillis would allow true correction of the original deformity by manipulation. In my experience elongation or division of the tendo Achillis is necessary in the majority of cases.

It may be argued that stretching is ideal, and that elongation of the tendo Achillis leads to retraction and diminished excursion of the calf muscle. On these theoretical points I agree, but practically I find that after a certain point is reached further simple manipulative efforts produce a convexity of the sole rather than a true descent of the heel. At the age of 4 to 6 months we therefore usually find it inadvisable to practise elongation of the tendo Achillis, and if necessary divide the resisting posterior ligaments.

The child will usually begin to walk at the end of one year. Walking when a position of over-correction has been obtained is an ally in preventing recurrence of deformity. The question of treatment during the second six months of life is important. When complete over-correction of the deformity has been maintained for two months, relaxation under observation may be allowed for a time. If there be any tendency to relapse, the over-corrected position should be maintained until walking is established. If there be no tendency to relapse, a normal weight-bearing position of the foot is maintained by plaster-of-Paris, and weight-bearing encouraged. Experience alone will teach us which patient should walk in the over-corrected position, and which in the normal weight-bearing position. Release will seldom occur if the over-corrected position is maintained. But if the child with freedom maintains the voluntary power of dorsiflexion and eversion of the foot, the normal weight-bearing position will be maintained.

I have purposely included relapsed and untreated cases amongst those which should respond to treatment on general lines. In many of the cases generally looked upon as relapses the deformity recurs because a true correction has been maintained. In many of the cases generally looked upon as relapses the deformity recurs because a true correction has been maintained. In many of the cases generally looked upon as relapses the deformity recurs because a true correction has been maintained.

When the child has walked for three months in plaster freedom may again be allowed under observation. Full dorsiflexion and eversion should be maintained during the night by a specially moulded splint. This may be made of plaster-of-Paris or celluloid. The important point is that its application should only be possible if the normal degree of eversion and dorsiflexion of the foot is present. If there be a tendency to relapse, further fixation in plaster-of-Paris in the over-corrected position will be necessary for several months. The case which has shown a tendency to relapse may, on discontinuing over-correction by plaster-of-Paris, be fitted with a special cork insole. This is so moulded to the foot that it maintains the necessary degree of over-correction whilst allowing movement at the ankle-joint and exercise of the muscles controlling eversion and dorsiflexion of this joint. When the muscles controlling eversion and dorsiflexion of the foot are strongly developed, and the depression in front of the external malleolus is present, this insole may be discarded. Subsequent treatment will then be conducted on general lines.

#### Relapsed and Untreated Cases.

Release to the original deformity is a more difficult problem than the untreated case. Usually the same lines of treatment will be effective; an anaesthetic is necessary, and the use of the Thomas wrench allows us to impart the requisite force to our manipulations. This procedure will be repeated more than once if necessary. The resulting position of correction is maintained by a closely applied plaster splint. In most cases we must at first utilize the flexed knee to maintain the abduction and true eversion of the foot at the mid-tarsal and subastragaloid joints. It will be necessary to maintain this position of full correction for four to six months, when a short walking plaster may be allowed. When this plaster has to allow of walking with the foot in the position of dorsiflexion and eversion the fore and outer part of the sole should be thickened so as to give the child a flat surface on which it can walk. Sometimes it is found that the child walks in the short plaster with the toes pointed inwards, even though the true position of correction seemed to have been obtained. Many hold that it is due to an internal rotation of the tibia and fibula below the knee, and that an osteotomy of these bones is sometimes necessary to correct this very troublesome deformity. My own belief is that this in-toeing is due mainly, I might almost say entirely, to a failure to obtain true correction of the deformity. I think that the main cause is that the corrective force has not been entirely exerted on the mid-tarsal and subastragaloid joints, and that this force has been responsible for a rotation outwards of the body of the astragalus in the ankle-joint. In early cases, where care is taken to maintain a pressure on the outer side of neck of the astragalus equal to the corrective force, this is practically an unknown complication. If it be present, the operation of osteotomy of the tibia and fibula, with the necessary outward rotation of the lower fragments, will correct it. The following operations are practised in selected cases to guard against relapse.

*Transplantation of the Tibialis Anticus*—The natural action of this muscle is to dorsify and invert the foot. By its transplantation to an insertion on the outer border of the foot it will not only cease to be a factor in producing recurrence of the deformity, but will act strongly by its new insertion as a dorsiflexor and evolver of the foot. Where a true correction of the deformity has not been obtained, this transplantation of the tibialis anticus will be helpful in preventing or delaying a recurrence of deformity. Where a true correction of the original deformity has been obtained it is unnecessary and will lead to cause a bred eversion of the foot. *Bankart's Operation*—By this operation the position of over-correction of the foot is maintained by the insertion of a strong silk ligament passing from the outer border of the foot to the tibia. I was very much impressed with the clinical results which Mr. Bankart presented at a recent meeting of the British Orthopaedic Association. It is an operation which obviates the necessity of prolonged plaster fixation to prevent relapse. This gives it a definite place in the treatment of club-foot, when prolonged treatment and observation are not possible.

arthroplasty of the hip-, knee-, or ankle-joint in any case of osteo-arthritis. In my opinion, in all these joints a better functional result is obtained by the operation of arthrodesis. Arthroplasty is essentially the operation for osteo-arthritis of the great toe-joint (hallux rigidus); the procedure of a limited excision of the head, trimming up and filing of the surface, and the insertion, where possible, of a flap of fascia, is so well known that it needs no description. It is important to bear in mind that this operation is not a trivial one and must be carefully performed, and that it should be followed up by after-treatment lasting for at least two months, the toe-joint and the transverse arch of the foot being supported by taping.

(c) *Arthrodesis*.—This is the most generally useful of all operations for joints affected by arthritis deformans which remain chronically painful in spite of other treatment, and for those in which function is seriously interfered with by progressive deformity. It is most often applied to the hip- and knee-joints. In the hip-joint it is commonly considered a very severe operation involving much shock. If the joint be immobilized in plaster-of-Paris at the time of the operation the shock involved is much less than is commonly believed, and there is no reason why the procedure should not be applied to people up to the age of 55 or 60, if their general condition is good. There are several methods of arthrodesing the joint. That which I personally prefer is to approach the joint by a Kocher's incision, turn the head right out of the acetabulum and trim it up, removing all cartilage and osteophytes until a spherical surface of bare bone is produced. A corresponding raw cup is then prepared in the acetabulum with mallet and gouges and finally cleaned up with a rotating burr of the shape and size of the femoral head. The head is then replaced in its socket, the wound sutured with drainage, and the limb fixed in plaster-of-Paris at about 5 degrees flexion and slight abduction. The patient must remain in bed in the plaster for six weeks. A short plaster is then applied in which the patient should walk for the next four months. In cases in which I have started to remove osteophytes from the head of the femur and found that the articular cartilage is eroded, I have completed an arthrodesis by the above method straight away.

In the knee-joint arthrodesis is suitable more particularly for unilateral cases in which the movement remains much limited and painful, especially if the knee has become flexed. In some cases such flexion deformity can be reduced by extension and splinting; in others, however, it will be found that the joint changes are such as to leave a mechanical blocking of extension. In these an exploration of the knee-joint must be carried out, and if the articular surfaces are much eroded an ankylosed joint will give the best functional result; a limited excision of the classical type without removing the entire synovial membrane is the best and simplest procedure. Much bone must not, however, be removed, as there is a far greater risk of non-union than exists in an excision carried out for tuberculosis in young subjects.

Arthrodesis of the shoulder is justifiable in occasional cases in which pain persists in spite of all other forms of treatment.

*Operations to Alter the Position of a Fixed Joint*.—From, I figure little comment. Those most often necessary are, osteotomy for a badly adducted hip, an osteotomy of the knee, and the removal of a wedge from the

1. In part of the carpus to correct a fixed, flexed wrist. In some of these, when the patient is under the anaesthetic it is found that a little mobility remains in the joint; it may then be questioned whether an arthrodesis should not be substituted for the other operation. In flexion of the knee, operations for division of the hamstring tendons, the attachments of the gastrocnemii and the posterior part of the capsule are sometimes required in order to straighten a knee in which sufficient movement remains to be functionally useful.

Orthopaedic Bush and Orthopa  
St. Bartholomew's Hospital, St. Bartholomew's Hospital.

I WISHED to open the discussion in order to explain the as secretary of the Section, in order to obtain the maximum benefit from the limited time at our disposal, I had asked speakers to confine their remarks each to a comparatively limited portion of the field, with the exception of Mr. Elmslie, whom I asked to cover the whole ground as a leader to others, and whom I should like to congratulate on the lucid and compact manner in which he has done this.

By agreement, I shall confine my few remarks to the subject of the less drastic operative procedures which may be carried out for this disease.

Irrespective of the pathology, the treatment can be divided into two definite parts—that of the causative disease, and that of the local condition. The pendulum has swung from inefficient recognition and treatment of the former to efficient treatment of this and neglect of the latter. When once we are satisfied that the causative disease is adequately treated, the remainder of the problem is purely orthopaedic. It is, in fact, traumatic. Like any other piece of mechanism, a joint, if forced to work under unsound mechanical conditions, tends to become increasingly disorganized owing to abnormal stresses and inaccuracies of surface. The trauma may be one of three kinds: origin in external violence, causing localization of the disease in certain joint from diminished resistance; due to malposition and consequent abnormal strain; or internal, from current trauma from structural defects within the joint.

As growth and nutrition are dependent on function, provided that the supply of toxin be cut off and the joint surfaces not very severely damaged, if our skill were sufficient to reproduce by operative means a joint so perfectly shaped as to be mechanically sound, and ensure that that joint be exposed to no abnormal stress, the disease would cease to progress.

In the knee-joint the presence of loose bodies, ragged semilunar cartilages, lipomata arborescentia, and osteophytic outgrowths provides just that adverse weight in the balance which prevents natural function from exercising its restorative power, as these structures render the joint unsound, and also the nipping of loose structures between the joint surfaces and the continual impingement of osteophytes on the lateral expansions of the vasti give pain and limit free function.

I would plead, therefore, that as soon as the toxic element is checked, early operative measures should be considered, especially where the skiagram or some special clinical feature indicates the presence of the conditions mentioned above. Like others, in selected cases, I have had good results from extensive "spring cleanings" of joints through large incisions, but I feel that we should forestall the necessity of these by operating earlier.

It will be argued that patients will not readily submit to operative measures while their disease is in its early stages, and also that the age of those patients commonly afflicted with this disease makes surgeons loath to operate. Against this I would argue that the risk of sepsis in joint operations is now negligible; there is little shock in the less drastic operations and convalescence is rapid; and, finally, that we are attempting to discover ideal methods of treatment, trusting that when we can advise the methods whole-heartedly, our patients, being but human, will be more inclined to be guided by us.

The methods I employ do not differ materially from those described by Mr. Elmslie. In the knee lateral incisions suffice in the early stages and a split-patella operation is rarely needed, but should be employed without hesitation when required. Mr. Elmslie speaks of six weeks' extension as after-treatment, and this is certainly advisable after a drastic operation, but when an early operation is performed it is my practice to treat, say, the knee in exactly the same way as I should a simple removal of a semilunar cartilage and to pay the same attention to restoration of muscular power as I should in that case.

copious discharge of blood from the mouth and nostrils. This was repeated three hours afterwards.

7. We should insist on descent of the os calcis by division

One other point: Mr. Elmslie speaks of incision and lavage of joints as being suitable to acute conditions only, and has little faith in such treatment in chronic cases. I agree; but there is a certain type of arthritic joint which is definitely benefited by this. Chronic arthritis of the proliferative type with chronic effusion, where the causative disease is intestinal (typhoid, dysentery, or *Bacillus coli*), responds well to this treatment. I cannot explain this, but have found it true. At first I opened the joint and washed it out with saline, but after reading in 1920 of the employment by Rocher of Bordeaux of ether to wash out joints through a puncture with trocar and cannula, I employed ether lavage through an open incision. Cases other than intestinal were disappointing, but the intestinal cases were all improved. The treatment is empirical, and whether the effect is due to induced hyperaemia, sterilization, or some other factor, it is hard to say. I am inclined to believe that the free admission of air to the joint is of value. Be that as it may, I can confidently recommend this treatment, in this type of case.

## II.—HARRY PLATT, M.D., M.S., F.R.C.S.

Senior Surgeon, Ancests Hospital, Manchester; Consulting Surgeon, Grangecliffe Hospital (Ministry of Pensions), and Ethel Hedley Hospital for Crippled Children.

IN accordance with the suggestion of the officers of this Section my contribution will be limited to a consideration of the operative treatment of osteo-arthritis of the hip-joint. Although in the majority of cases this is a mono-articular affection, it is not uncommon to find evidence of early arthritic changes on the so-called healthy side. It is important to examine the patient very carefully with this in mind, as the choice of the appropriate operative procedure and its scope will be influenced to some extent by the possible existence of a bilateral lesion. It should hardly be necessary at this date to dwell on the now well known fact that the term *morbus coxae senilis*, so often applied to the affection under consideration, is a misnomer. We may encounter the typical picture of osteo-arthritis of the hip at all periods of adult life—the arthritis deformans juvenilis, the common osteo-arthritis of middle age, and the classical osteo-arthritis of old people.

An increasing familiarity with the living pathology of this condition in its various phases, acquired as a result of a considerable number of operative exposures of the deformed joint, gives one a clear appreciation of the real mechanical significance of some of the outstanding pathological changes. Thus there is a tendency to regard the marginal osteophytic deposits as the essential cause of the limitation of mobility and pain. This conception, to my mind, is erroneous. In the florid arthritis deformans of the hip the dense infiltration of the capsule, which becomes shortened and adherent to the femoral neck, together with the expansion and mushrooming of the femoral head, constitute the main obstacles to free mobility. Later on, with the development of an adduction contracture, and the more advanced degenerative changes in the articular surfaces, the reason for the mechanical block is obvious. The severe pain is dependent on the friction and crowding together of the two eburnated bony surfaces from which every trace of cartilage has usually been lost at an early date. From such considerations it will be seen that the operation of simple *chilotomy* is founded on an illogical basis. But the removal of the osteophytic rim of the acetabulum as part of a free excision of the infiltrated capsule is a conservative procedure of undoubted value in the early stages. I have done this on a few occasions where the amount of deformation of the joint did not seem to warrant the more radical operations of excision of the head of the femur, or arthrodesis. It is fair to recognize, however, that there is one type of case, admittedly rare, where simple excision of the osteophytes alone is exceedingly effective. These are the hip-joints which show large isolated bony outgrowths of the staccate variety, growing from the acetabular floor or from the margin of the femoral head. Such bizarre changes are atypical, and are not usually associated with advanced deformation of the femoral head or extensive loss of articular cartilage.

In actual surgical practice we are generally called upon

to deal with osteo-arthritis of the hip in the matured stage in a patient who has passed through some years of ineffective treatment for so-called "staccata," and who is becoming progressively crippled. The clinical picture varies considerably; many individuals look upon the limitation of mobility as a minor affair, but find the constant pain with its repeated severe exacerbations absolutely intolerable; in a smaller number (I am quoting my own experience) pain is a less conspicuous symptom, but the increasing stiffness is much resented. It is thus very necessary for the surgeon to appreciate the disability from the patient's own point of view.

Our collective experience of the late results of the major operative procedures employed for this condition has taught us that the majority of patients are well satisfied with a painless bony ankylosis of the hip. Thus as a fundamental consideration the operation of *arthrodesis* is to be regarded—in theory at least—as an ideal procedure. I feel, however, that there are certain objections to this operation in the case of older patients. In order to ensure adequate bony fusion of the femur to the acetabulum it is essential to remove in their entirety the layers of dense sclerosed bone which now represent the articular surfaces. This is accomplished without much difficulty after the femoral head has been fully dislocated. The operation, however, tends to be a lengthy one, and the duration of the anaesthesia is increased by some twenty minutes at least if a plaster-of-Paris spica be applied at its conclusion—a step which one feels is desirable, as Mr. Elmslie suggests. For these reasons arthrodesis, in my opinion, is applicable only for the younger or more robust patients. It is in those older patients for whom we consider arthrodesis a serious risk that the operation of *excision of the femoral head* finds a definite place. I have practised it now in some twenty cases with a clear appreciation of its limitations, but with the firm belief that in picked cases it is well worth while.

The details of the technique I follow have already been described in this JOURNAL (April 29th, 1922). The essential features are: (1) excision of the mushroomed femoral head; (2) abduction of the femur so as to bring the stump of the neck (previously rounded off) into the acetabulum; and (3) fixation of the great trochanter (which has been detached as part of the anatomical exposure of the joint) to the femoral shaft at a lower level, thus acquiring a position of mechanical advantage. The operation can be carried out rapidly, and I believe that it is much less provocative of shock than an efficiently performed arthrodesis. Its outstanding virtue is the relief of pain which follows; in addition the malposition of the joint is corrected, and a certain range of mobility is retained. In my earlier cases I was content with a relatively conservative removal of the femoral head, but now I advise and practise a much more generous resection. This is especially necessary where the opposite hip is the seat of a very early arthritic process.

Although as part of this discussion one has dealt with major operative procedures in some detail, it is desirable to emphasize the fact that, taking osteo-arthritis of the hip as a whole, it is only in a small proportion of cases that, after mature deliberation, we carry out such operations.

## III.—D. McCRAE AITKEN, F.R.C.S.,

Surgeon, Ministry of Pensions Hospital, Shepherd's Bush, and Shropshire Orthopaedic Hospital.

MR. ELSLIE, in opening this discussion, very properly laid emphasis on the septic or toxic factor in the production of the numerous varieties of osteo- and chondro-arthritis which can be quite fairly included in the vague term "arthritis deformans." Although Aphrodite may have risen complete and perfect from the sea foam, that is not the usual biological procedure; we expect to find an ovum at the beginning of life, and in the same way we may expect to find very small beginnings which are quite different in appearance from the fully formed picture of the disease found at an autopsy. Sir Arthur Keith, in his account of Hugh Owen Thomas,<sup>1</sup> points out that he started a new school of bio-pathology, as distinct from the Hunterian school of micro-pathology; he studied the gradual

[illegible]

growth of crippling conditions in the living and devoted his life to the prevention of the development of crippling diseases.

In pursuit of this idea, I maintain that we as orthopaedic surgeons discussing this large subject must look for the beginnings of the trouble, and, while we cannot omit the aid of the physician and the expert in the production of vaccines, our own particular *métier* is dealing with the traumatic element. My firm personal belief is that trauma is the actual cause of deformity in every case of arthritis deformans. The toxic or septic agent causes inflammation with its attendant hyperaemia and congestion in and about the joints. In 1863 Hilton published his lectures on *Rest and Pain*; at the same time Hugh Owen Thomas was devising splints to put joints at rest without necessarily having to put the patient to bed. The marrow of the whole matter is to be found in correlating the teachings of Hilton and of Thomas. The Liverpool school will keep the teaching of Thomas green for years to come. Is Hilton honoured in his own school as he should be?

Following Thomas's method of attacking the subject, I would divide the procedures of the surgeon into two groups—the first, bloodless methods; and the second, methods by open operation.

### 1. Bloodless Procedures.

I recognize four types of procedure, which I shall take in order of severity:

(a) Prevention of mechanical injury to pads of fat and to congested synovial membranes by suitable splint. One case suffices to illustrate this. We are all familiar with the patient who complains of pain in the middle of the front of the knee after walking, and especially of trouble in negotiating stairs. On examination it is found that full extension by the surgeon causes pain and that the patient will not voluntarily extend through the last few degrees, but the  $x$  rays show little or no osseous change. All the mechanical help he requires is a knee-cage adjusted to prevent full extension which nips the congested structures in the front of the joint. The patient then finds that he can walk with less pain or none at all, and in the meantime the physician gets a fair field for his therapeutic measures.

(b) Cases in which the  $x$  rays still show very little osseous change but there is a definite deformity, due largely to shortening of muscles, usually flexor muscles, the result of long retention of the joint in wrong position. Probably the source of ineffective trouble has been already dealt with by the physician, but the orthopaedic consideration of the case has been omitted. This type requires correction of the deformity under an anaesthetic, followed by strict fixation in the corrected position, until adaptive changes have occurred and the correction is thus established.

In both these types re-education of the weaker groups of muscles is an essential part of the treatment.

(c) Cases in which the  $x$  rays show hypertrophic changes round the margins of the joint, but the actual weight-bearing surfaces seem clearly defined. For example, at the hip-joint the patient complains of pain after walking almost more than when walking. On examination there is a limited range of movement free from pain; but an attempt to force the movement beyond this causes pain. In many of these cases the pain is caused by stretching adhesions which have formed about the joint and not by grinding of inflamed joint surfaces. If the surgeon is satisfied on this point and is also satisfied that the source of infection is cured or under control, then the adhesions may be broken down without fear of lighting up fresh inflammation, and this in many cases increases the range of movement and so relieves the pain, which is due to tension on adhesions.

(d) Cases in which obstructions within the joint are occasionally amenable to treatment by manipulation. For example, cases of osteo-arthritis of the knee with bony and cartilaginous masses within the joint so situated that the patient cannot bear weight on the knee can sometimes be relieved by a manipulative treatment to get the masses moved to some part of the knee in which they cause no trouble.

I have been privileged to see and assist Sir Robert Jones manipulate several such cases. Many of the cases have been very satisfactory to the patients and most surprising to me. I do not suggest this as a routine procedure, for it requires more judgement in the selection of cases than I feel I have yet acquired, and it requires some courage to face the situation if the procedure is not successful.

### 2. Open Operations.

These, I think, fall into the following categories:

(a) Operations involving removal of soft parts which have become thickened by repeated injury *plus* the congestion caused by toxic influences and have become mechanical obstructions to movement. Such operations are commonly performed at the knee, less often at the ankle, about the head of the radius, more rarely at the wrist-joint. The procedure is in every way comparable to removal of a crumpled semilunar cartilage at the knee.

(b) Operations for the removal of limited portions of bone or articular cartilage which are hypertrophied and causing obstruction and pain. These cases fall into two subdivisions:

(i) Those cases in which overhanging lipped edges of joint surfaces obstruct the free movement of tendons or aponeurosis, causing snapping of the joint with pain and considerable disability. A common example of this is found along the margin of the articular surfaces of the condyles where outgrowths of bone obstruct the free movement of the aponeurosis of the vastus muscle. Mr. Verrall removes these, leaving a raw surface of bone which he treats with wax. My procedure is, wherever possible, to leave the articular cartilage, but to cut away subjacent bone and then press down the cartilage so that the edge of the articular cartilage meets periosteum; thus I try to leave no bare or exposed bone within the joint. Of course, all masses of congested fat and synovia are removed.

(ii) The second class is where the outgrowth of bone and cartilage impinge on the opposite bone. The most common example of the type is to be found at the anterior lip of the articular surface of the tibia. In the skiagram [exhibited] the bone as well as the cartilage may be seen heaped up in a ridge or crest. On opening the joint the cartilage is seen to be red and hyperaemic and a similar hyperaemic line is found opposite it on the condyle. Behind this crest there is usually a pocket of hyperaemic soft parts and, perhaps, remnants of a semilunar cartilage. These should be removed as a matter of routine. But here again I cut away a wedge of bone under the redundant edge and depress it. The fact that the patient allows full extension of the knee immediately after the operation and gets up and walks with comfort eight or ten days later is to me a satisfactory proof that the operation clears away the cause of his trouble, and I think the avoidance of bare bone within the joint diminishes the risk of subsequent adhesions.

I understand others will deal more fully with the questions of arthroplasty and arthrodesis, so I may close with only one more remark. The treatment of the source of infection must not be omitted and should precede treatment by open operation, but may run concurrently with treatment by rest in splints.

### IV.—C. MAX PAGE, D.S.O., F.R.C.S.,

Surgeon to Out-patients, St. Thomas's Hospital.

I propose to limit my remarks to the practice and results of arthrodesis of the large joints of the lower extremity.

The operation of arthrodesis is certainly the most radical and final method of dealing with the condition under discussion. It cannot be regarded as ideal, in as far as the function of the joint is completely eliminated. Moreover, though the production of a complete ankylosis removes all pain in the joint affected, it exposes neighbouring joints to unusual strain and may be productive of secondary changes and pain in them.

One cannot but feel that in order to size up the relative value of the various operations for osteo-arthritis at present under trial we have need of the careful record of a series of cases over a prolonged period. I confess that I am sceptical as to the number of radical cures which can be looked for from what may be termed the minor operations.

In regard to the operation of arthrodesis, I have practised it in some 30 cases involving the knee and in 27 involving the hip-joint. These operations have been carried out too recently to make it possible to assess their final value.

The operation of excision of the knee to produce bony ankylosis is a straightforward one and need not be further discussed. Its immediate results are certainly most satisfactory, and from general experience the fixation does not appear to involve severe stress on neighbouring joints.

In the case of the hip an arthrodesis is not so easily

effected by operation. After the trial of several methods, I have come to the conclusion that it is best to approach the joint by means of the Smith-Petersen incision. The head of the femur is completely dislocated forwards after incising the capsule of the joint; the head of the bone is then denuded of all cartilage and the compact bone cut away with the broad gauge until cancellous bone is exposed; the acetabular cavity is then treated in the same way. The clearance of the acetabulum is not always easy in a stout patient, but is certainly simpler when the above described incision is employed than when the posterior or external route is adopted. At the completion of the operation, the head having been replaced in the acetabulum, the limb is fixed in a position of abduction and slight flexion in a plaster-of-Paris spica. In all cases in which there is much spasm of the adductors I tenotomize them freely in order to facilitate the maintenance of position. I have adopted the same after-treatment as is advocated by Mr. Elmslie.

I have carried out this operation in patients whose ages range from 53 to 70. My impression is that in young men it is the operation of choice. In older patients a certain proportion develop pain in the sacro-iliac joints and lumbar spine. I think that for these other cases the procedure advocated by Mr. Platt is a more satisfactory one.

It is often stated that operations of this nature are associated with serious shock; I have not experienced this complication in any instance either during operation or in the twenty-four hours following it.

#### V.—W. ROWLEY BRISTOW, F.R.C.S.,

Orthopaedic Surgeon, St. Thomas's Hospital.

I would express myself in agreement with most of what Mr. Elmslie has said in his opening remarks.

With regard to the surgical treatment of osteo-arthritis of the hip-joint, I would emphasize the fact that it is absolutely necessary to assess accurately the patient's disability before deciding to perform a major operation on the hip. The question to be answered is: will such operation satisfy not the surgeon, but the patient? If the degree of disability is great, and above all if the pain is very severe and remains unrelieved by simple treatment, undoubtedly operation is both justifiable and indicated, and I would suggest that the amount of pain complained of should in most cases be the deciding factor. It must be recognized that the result either of excision of the hip or arthrodesis is not a perfect limb. Some speakers favour fixation, some excision. In my opinion, in younger patients fixation (arthrodesis) is the operation of choice, because the loss of hip-joint movement is to some extent compensated by movements of the lumbar spine. In old subjects I think excision gives the better result. The fixation of the hip in these patients, in some instances at least, gives rise later to pain in the lumbar spine and neighbourhood of the sacro-iliac joints, which pain may be as bad as that for which the operation was originally undertaken. I would agree that forcible mobilization under an anaesthetic and a weight-relieving caliper or walking appliance are methods which have great use, and for the application of which there is a large field.

With regard to osteo-arthritis of the knee, we are, I think, all agreed that arthrodesis of the knee-joint is a most satisfactory operation, and should invariably yield a good result. The pain is cured and the patient is enabled to get about with comfort. But in the case of marked changes in both knee-joints with fixed flexion deformity, is it justifiable to fix both knee-joints? My impression is that a patient so treated is better off than one with a deformed and painful knee, recognizing at once that the ultimate disability must be severe. I would like to hear an expression of opinion on this point.

With regard to the more tentative operations which have been mentioned it is difficult to be certain that any beneficial result is due to the operation. Naturally, a loose body or torn cartilage should be removed even in the presence of some degree of arthritis. But the mere opening up of a joint and washing it out should, I think, only be resorted to in rare instances.

#### VI.—SIR ROBERT JONES, K.B.E., C.B., F.R.C.S.

THERE are only a few points which I should like to emphasize in connexion with the treatment of osteo-arthritis. The first is the paramount importance of resting a painful joint. Incalculable harm is done by the advice which is sometimes given to move the joint for fear it should get stiff. In the earliest stage of trouble in the knee, in which the patient finds that he cannot fully extend the joint without pain, but that flexion is painless, the simple device of fitting a knee-cage which prevents full extension eliminates that part of the movement which is harmful, so securing the required rest without laying the patient up.

In later stages, for example in the hip-joint, cases are found with great deformity and but little pain, and vice versa. These require careful discrimination. In some cases there may be comparatively free mobility in certain directions with marked limitation of movement in another. This limitation of movement is often due to periarticular adhesions which cause pain when they are stretched. Hutton used to manipulate these cases, breaking down the adhesions, with great advantage to his patients. The condition is particularly common in hunting men, who often complain of the limitation of abduction. Manipulation to break down adhesions and increase abduction often enables these patients to sit a horse without pain.

In cases of arthritis of the hip of the hypertrophic type, with much pain which persists in spite of rest, open operation may become necessary. My experience of dislocating the hip in order to reshape the head of the femur is that it is provocative of much shock, which is a serious consideration, for these patients are usually elderly people. Therefore I would advocate an operation which can be performed rapidly without much shock.

In unilateral cases with free movement of the other hip a firm painless ankylosis is often the result to be found. Approaching the hip-joint by the Smith-Petersen incision, a large part of the head and acetabulum can be stripped of cartilage without dislocating the joint, and then, as firm arthrodesis is often difficult to obtain, I usually detach pieces from the ilium round the acetabulum to fill the gap between the head and the acetabulum.

In cases where both hips are affected with stiffness and pain it is desirable to have one movable hip, and also desirable to have as little shock as possible. If a rapid excision is required the same approach may be used as in that for arthrodesis: the neck of the femur is divided, the enlarged head removed, and the stump of the neck placed into the acetabulum. The limb is then placed in abduction. On some occasions I have produced a pseudo-arthritis of one hip by removing about 1½ in. of the femur just below the great trochanter and placing a little muscle between.

In old people with very painful hips it would be sufficient to perform an operation in which the head of the femur need not be removed, and this would consist of a separation of the trochanter, a removal of a portion of the neck, and a fixation of the trochanter, with muscle attached, to the portion of the neck contiguous to the head which is not removed from the acetabulum.

With regard to ankylosis of both knees, my experience is that the disability is not so terrible as might be expected. In cases where both knees are stiff and painful I prefer to straighten one knee and ankylose the other in a slightly flexed position.

Mr. ELMSLIE (in reply) said that the term "arthritis deformans" had been originally used in the suggested topic for discussion. It was conveniently wide. Treatment by rest and manipulation was left out of discussion by definition, but he employed these methods much. He had no anxiety over shock, which was avoidable by a good anaesthetic and immediate relief of pain after operation. After excision of the knee, plaster should be applied from foot to pelvis. Double ankylosis of the knee was not so terrible as people thought, especially in a child. Physicians should be educated to believe that patients would stand shock, that operations were simple and safe, and that excessive temporizing with mechanical defects was unsatisfactory.

## ACUTE RICKETS IN LATE CHILDHOOD AND ADOLESCENCE.

BY

E. LAMING EVANS, C.B.E., F.R.C.S.

THE experimental work on the etiology of rickets in animals, leading up to that of Mellanby in 1918, and carried on since that date by a large number of investigators, together with the truly scientific methods for the prevention and treatment of rickets in infants afforded by Professor Pirquet to Dr. Chick and her colleagues in Vienna, has added fresh interest, not only to the question of rickets in infancy, but also to the sporadic cases of rickets occurring in late childhood and adolescence. In addition, the great war has afforded us increased material of late rickets, and has tended to elucidate the problem of the connexion between that disease and hunger osteomalacia.

The question arises: Have recent experimental and clinical observations brought us nearer to the solution of the problems whether late rickets can arise *de novo*, or is merely a recrudescence of an earlier rachitic state, and whether the etiology of late rickets is identical with the infantile form?

I have used the word "acute" in the title of this communication so as to include a general metabolic change and to exclude the ordinary adolescent deformities such as scoliosis, genu valgum, coxa vara, etc. In this sense it is synonymous with the term "florid" used in infantile rickets. I do not use the term as implying haemorrhages which are due to a scorbutic element coexisting with the rachitis.

The question whether acute rickets occurring in adolescence is a recrudescence of a former rachitic metabolic vice or is a new metabolic change has occupied the minds of former reporters. To differentiate the two conditions reliance has been placed upon the permanent stigmata of rickets as evidence of a former rachitic state. Briefly, such stigmata consist of stunted growth, shape of the cranium, rachitic deformities, especially of the long bones. No reliance can be placed upon family history, for we all know the parental surprise when the true nature of florid rickets is first communicated either to the careful or careless mother. But the milder forms of infantile rickets are common and so readily curable with advancing age, leaving no permanent stigmata, that it is an impossible task to exclude a mild degree of early rachitic metabolic change at the time of life when late rickets is prone to recur. I should suggest that the real importance is to differentiate between the infantile form which has continued into late childhood uncurred and in which the stigmata are so well marked as to be with difficulty unrecognized, and those cases of florid rickets which are unassociated with evidence of former rickets.

### Definition.

The essential feature of rickets is a disturbance in the metabolism of the growing organism in which the calcium and phosphorus in the circulating fluid are unbalanced, in consequence of which calcium is no longer deposited in bone. The blood changes consist of a diminution in the organic calcium or phosphorus, or both. Normally, serum contains 10 mg. of calcium and 5 mg. of phosphorus per 100 c.cm. One or other may be diminished in rickets. Thus two forms of disturbance in salt equilibrium may be present: (1) Calcium may be low and inorganic phosphorus may be about the normal; (2) phosphorus may be low whilst calcium is about the normal. In the low calcium form of rickets the symptom complex of tetany is prone to occur.

The first detectable sign of rickets is probably the diminution of the inorganic phosphorus or calcium of the blood. A more systematic examination in the future may reveal that childhood is not infrequently the seat of a low calcium and phosphorus blood state, a pre-rachitic condition which only exceptionally proceeds to a state recognizable by x-ray or clinical examination of the bones as rickets. Hess<sup>1</sup> has pointed to a seasonal variation in the calcium and phosphorus contents of the blood, corre-

sponding to the seasonal variations in the occurrence of rickets. Further observations are required on this point.

The subjective character of the changes in the soft tissues exclude their adoption as criteria of the disease, which is admirably demonstrated by the x-ray appearances of the ends of the long bones. The changes at the ends of the long bones are so characteristic and so easy of demonstration that they are now universally used as the criterion of rickets.

The x-ray appearances in the long bones in florid rickets depend upon the decrease of calcium salts and the increase in osteoid tissue. The shaft presents: (a) thickening of periosteum; (b) enlargement of medullary cavity; (c) abnormal curves, corresponding to mechanical causes. The epiphysis shows, in place of a definite well defined shadow, a cloudy area containing one or more ill defined centres of ossification. The diaphyseal end is ragged at its attached surface and is broadened, overlapping the epiphysis, especially upon its weight-bearing side. The cartilage of conjugation may show a linear ossification bisecting the cartilage into two thinner discs. It is an early sign of recovery, and is known as the line test.

As our present knowledge of the causation, prevention, and cure of rickets is based upon experimental work on animals and clinical observations on man, objection may be raised as to the identity of experimentally produced rickets in animals and that occurring in the human body. The evidence is overwhelming that the conditions are the same. The skeletal lesions are identical macroscopically and microscopically; the blood changes are the same; tetany may accompany both forms; the same remedies are effective in both.

### Age Incidence in Rickets.

The age incidence of rickets is important in explaining the infrequency of cases of late rickets. The premature child is peculiarly susceptible to rickets, even when well breast-fed; the earlier premature child is more liable than the later premature child, and the explanation has been offered that the rate of subsequent growth is inversely proportionate to the age of the individual. In early infancy the same rule applies, and so on in childhood. Rickets only occurs during growth. The calcium and phosphorus blood contents become more constant and tend to smaller variations from the normal with increasing years.

### Seasonal Variation in Rickets.

There is a well marked seasonal variation in the onset of rickets. Children born in the autumn are more liable to rickets than children born in the spring. Likewise rickets tends to a spontaneous cure during the summer months.

### Geographical and Racial Distribution.

Certain facts are well established. The negro child in Africa does not develop rickets, yet the negro and Italian children in American cities are especially susceptible. Chinese and Japanese children rarely develop rickets. Esquimaux children are free, though they live in dark huts, and, for half the year, in Arctic twilight.

### Our Present Conception of the Metabolic Change in Rickets.

The problem presents enormous difficulties for its solution. Two factors appear to be effective in regulating the salt absorption by bone tissue:

(a) A factor X, which is generally present in association with fat-soluble A and which has hitherto been generally known as fat-soluble vitamin A. The reasons that the antirachitic X and fat-soluble A are not identical have been shown by Hopkins,<sup>2</sup> who oxidized cod-liver oil for four hours at 120° C., destroying the A but not X. Cod-liver oil contains A and X abundantly. Butter contains A but very little X.

(b) A radiant energy, which is present in the solar spectrum and emanations from mercury-vapour quartz lamp. Thus, the addition of X to the diet, or of radiant energy to the environment, invariably cures rickets if established, or prevents its development without change of diet or conditions of life.

The human organism appears peculiarly dependent on the presence of this radiant energy or its equivalent in

the food; for rickets may develop when the organism is deprived of them even though the diet be what is commonly considered well constituted. Thus rickets is a deficiency disease in the sense that radiant energy or a factor X is deficient.

#### Applications of these Principles in the Study of Late Rickets.

The number of cases of late rickets recorded before the war were relatively few. Thus Looser<sup>2</sup> collected some 60 in 1903, of which two-thirds occurred in females and one-third in males. No etiological explanation has been forthcoming, though valuable pathological material was demonstrated. The reasons suggested for the infrequency are as follows. Diet is more varied and exposure to sun more certain. In this connexion it is interesting to note that the experimental production of rickets in older animals is attended with greater difficulty, and that animals in the wild state never develop rickets. The records of Higier,<sup>4</sup> and of Hutchinson and Shah,<sup>5</sup> are therefore extremely instructive in this connexion.

Higier observed 3 cases of late rickets during the last years of the war in Poland. The ages ranged from 8 to 13; no signs of previous rickets were present. During the same period he observed many severe relapsed cases of infantile rickets and over 70 cases of hunger osteomalacia, at ages ranging from 19 to 56. One case, the youngest of the osteomalacia cases, aged 19, presented signs of late rickets in addition. He says:

"Nothing can be determined as etiological in the cases of late rickets except hunger and under-nourishment, and nothing helped so much as change and increase of the rations, together with cod-liver oil and phosphorus emulsion."

Discussing the relation of late rickets and osteomalacia he says:

"It is fairly probable, in view of the endemism of both, of the similarity of their clinical pictures, and of their coincidence in time and place, that the late rickets and the early osteomalacia are pathogenetically closely related the one to the other, perhaps even identical."

Hutchinson and Shah reported the following features from observations of cases of late rickets in the Nasik district of India:

- (1) It occurs in the well-to-do and not in the poorer classes; the former obtain a much larger supply of fat-soluble vitamin.
- (2) It occurs where the purdah or semi-purdah life is adopted.
- (3) It occurs in females only.
- (4) It occurs soon after the purdah life is adopted, without change of diet.
- (5) It does not occur in the poorer classes, whose diet is inferior but who do not adopt purdah.
- (6) In six cases, without change of diet or medicine, treatment on open-air lines relieved the symptoms.

According to our present conception of rickets the curative factors in the vicious metabolism were, in the Polish cases factor X, and in the Indian cases radiant energy.

I will now describe shortly two cases of late rickets, for the second of which I am indebted to Mr. W. R. Bristow.

The following case is under my care at the Royal National Orthopaedic Hospital.

Gerald P., aged 7½ years, was first seen in January, 1923. The history is that, in October, 1921, he had an acute gastro-intestinal illness, with which he was in bed for a fortnight. Three months later a swaying gait and weakness of the legs were noticed by the mother. He was an eight months child. As a baby he was not fed by the breast, but by cow's milk and lime water. He had had no previous illnesses.

**Family History.**—The height of the various members of the family is as follows: Father, 5 ft. 7½ in.; mother 5 ft. 2½ in.; sister Queen, aged 15, 5 ft. 1 in.; brother Derrick, aged 14, 5 ft. 6 in.; sister Rosemary, aged 11, 4 ft. 11 in.; Gerald (the patient) 3 ft. 5½ in.; sister Mosa, aged 6, 3 ft. 2½ in. A photograph of these brothers and sisters shows no deformity, but normally developed children. Gerald is thus the shortest member of the family but can scarcely be considered as stunted by earlier rickets.

**Gerald's Present Condition.**—Head: Some flattening of the vertex; no undue prominence of frontal or parietal eminences. Teeth: First dentition said to have appeared normally, but teeth decayed early; at present permanent central incisors, upper and lower, are about half-way erupted. Thorax: Well marked rickety rosary. Spine, clavicles, and shoulders normal. Elbows: No carrying angle present; arm and forearm are in same axis in flexion and extension. Wrists: Marked enlargement of the lower

epiphysis and adjoining diaphysis of radius and ulna. Hips: No physical sign of deformity. Knees: Epiphyseal and diaphyseal regions of femur and tibia enlarged. Genu valgum, 1½ in., and outward curvature of the tibiae, 2½ in., are present. The Wassermann reaction was negative.

This child has been treated for six months by cod-liver oil and a good general hygiene. In that time he has grown 3½ in., and his improvement is shown by the series of skiagrams taken in January, April, and July. In these the lower end of the radius and ulna, the lower end of the femur, and the upper and lower ends of the tibia show changes typical of florid rickets. The shafts show normal curves only, which is strong evidence that if any rachitic process occurred in infancy it was slight and spontaneously cured. The condition of the upper tibial metaphysis is interesting—for one inch it shows an osteoporosis and a thinned cortical shadow. This portion would correspond fairly accurately with the growth of bone subsequent to his attack of intestinal disturbance in October, 1921. The centres for the great trochanters are diffused and ill defined. In the cartilage of conjugation between the femoral head and neck an intracartilaginous line of ossification is clearly visible on both sides and points to the commencement of a spontaneous cure by January, 1923, when I first saw him.

The second case is one under the care of Mr. Bristow, who has kindly permitted me to record it in conjunction with the above case.

J. G., aged 14½, came under observation in May, 1922. She suffered from infantile paralysis in infancy, affecting the right lower limb, and was in St. Chad's Home for seven years previous to May 1922. Upon admission she showed distinct enlargement of the epiphyseal regions of the wrists and ankles. There were no other definite signs of old rickets in head, chest, or back. She was treated with heliotherapy and antirachitic diet.

#### X-ray Report.

June 3rd, 1922. Wrists: Splaying of diaphysis and cupping with granular outline, active rickets. Ankles: Active rickets.

September 12th, 1922. Wrists much improved; still some activity.

December 12th, 1922. Wrists recovered.

#### CONCLUSIONS.

No definite etiological factor can be brought forward to explain either of these two cases. An acute gastro-intestinal illness appears to have determined the commencement of one, whilst the other began after seven years in St. Chad's Home. This may have been due to dietetic monotony, though no other cases are known to have occurred. Yet we must remember that, in infancy, an apparently well proportioned diet may produce rickets in one child and not in another under similar conditions of exposure to radiant energy. It is possible that the crippling effect of a paralytic leg may have rendered her exposure to radiant energy insufficient. Her attack was noticed during the winter months, when both the food contents of X and radiant energy are low; and it is worth while noting that such ultra-violet rays as supply radiant energy fail to penetrate ordinary window-pane glass. Esquimaux who live without radiant energy for half the year do not develop rickets because there is an abundance of X in their food. Negroes and dark-skinned Italians in cities are peculiarly prone to rickets, because the pigment of their skin insulates them from radiant energy in a somewhat similar manner to window glass. Cod-liver oil, rich in X, has a marked curative effect in these cases.

Higier's cases may almost certainly be ascribed to a monotonous low ration deficient in X, and perhaps accentuated by a deficient exposure to radiant energy caused by weakness. Rickets in Poland is rare. In Hutchinson's cases X was abundant and absence of radiant energy was the sole cause. Removal from purdah and exposure to open air without change of diet cured the condition.

Whilst further facts must be collected before a definite cause of late rickets can be stated, there are reasonable grounds for suggesting that late rickets is produced by the same agents as infantile rickets—namely, an insufficiency of factor X or radiant energy, or both; that it is, in fact, a deficiency disease; and that it can be cured either by the addition of factor X to the diet or of radiant energy to the environment.

I am indebted to my clinical assistant Mr. Lambrinudi, F.R.C.S., for extensive bibliographical help, and to Dr. W. H. Coldwell for the radiographic investigations.

physician; and, as she points out, there are to be found brief but emphatic references to the healing agency of music throughout history. Of the several powerful influences capable of bringing about a stilling of inner strife, and strengthening a mind bewildered by chaotic thoughts and harmonizing the personality, she regards music as one of the most potent. More subtly, more rapidly, and more completely than any other agent which produces intense or high emotion, can music, Dr. Savill views call to mind the delightful biblical story of Saul and David: "And it came to pass, when the evil spirit from God was upon Saul, that David took an harp, and played with his hand; so Saul was refreshed, and was well, and the evil spirit departed from him" (1 Samuel xvi, 23). We may not have increased in wisdom since the days of old, but we have in knowledge, and Dr. Savill is able, in an interesting chapter, to enforce her arguments by references to the physiology of the emotions. Here she contrasts the effects of depressive or contractile emotions, such as anxiety and fear, which, when unduly prolonged, not only narrow the sphere of life but make for lowered vitality and disease, with those of the expansive emotions of joy and courage, which make for health, activity, and usefulness. She is of the opinion that music, with its power to replace the contractile emotions by those belonging to a different category, plays an important part for the assistance of suffering humanity. The physical effects on the organism of rhythm, expression, and harmony are fully considered in this connection.

The views expressed in this volume have a special quality because they are based on the personal experience of its author. The story of her musical conversion is of great interest. Up to the age of thirty she was not merely indifferent to music; it aroused sensations of boredom and fatigue, and her attitude was one of active dislike. She came at length to realize that something was lacking in her, that some unknown senses required development, and experimented with much pertinacity to acquire an appreciation of the beauties of sound. The moment came when life was given to the notes which had hitherto seemed dead, and Dr. Savill felt that she had been given the key to a new language. After this she made steady progress, and by persistent study found out for herself what is really great and of permanent value in music. Dr. Savill has the gift of being able to depict in words those intangible and elusive emotions and feelings aroused by music. The charm of her narrative does not depend, however, only on her descriptive ability, but also on her obvious sincerity and lack of affectation. She describes what she actually does feel and think; she is completely true to herself, admits when she is bored, and endearments by careful analysis, and reflection to discover the cause of her discontent.

One general criticism of Dr. Savill's views may perhaps be permitted—namely, that she scarcely appears to take sufficient into account the problem of individual differences. It is improbable that the mass of the people could be brought to her own level of musical culture, or even if they were that music would have the same spiritual significance for them. The meaning conveyed by music must be largely dependent on purely personal factors. Music, rather than a particular sort of music, is health-giving, and the simplest music—such as folk songs, popular airs, hymns, dances—may be as profoundly energizing and beneficial to simple (in a musical sense) people as the best classical music. We may perhaps even say that many great comedians have by mirth and song given a new outlook to life to many thousands of people and sent them to their usual task encouraged and refreshed. Whether music is used for the individual from the therapeutic point of view or whether it is considered from the social point of view it must be of such a character as to meet the needs of the person or persons for whom it is intended. What we can unreservedly recommend this book. It does not think they ought to need or like must not be too much in the foreground.

### CATARACT EXTRACTION.

Dr. S. CARVER SMITH'S book on *Heart Records, their Interpretation and Preparation* is described as an elementary guide for those who would investigate the most recent methods of heart examination. By far the larger part of the book deals with electro-cardiography, and the subject is treated in a most systematic manner. The student is taken over the various steps in the analysis of the curves in great detail and with the help of a lavish display of very clear graphs the reader ought to be able to follow the instructions with ease. Much information which will be of use to the beginner is offered in a very practical manner and should help him to avoid many pitfalls in the carrying out of the ordinary technique. Thus many useful hints are given regarding the management of the patient, the developing and printing of the records, while the author explains his method of filing and keeping them. The instrument described is an American model and much of the information regarding its care and operation, though general and applicable to any instrument of the kind, is of more value to one using the special apparatus described. There is no doubt that the book will be of considerable value in the author's country, where the public is more likely to demand cardiographic records with the idea that they are thus getting the last word in diagnosis. We have the feeling that a smaller book on the same lines would have been welcomed by many in this country when making their first attempts along this line of investigation.

A smaller section of the book treats of polygraphy, but it could well have been omitted as it detracts from the value of the book as a whole. The illustrative tracings are not good, the waves are not marked, and we feel that the beginner would be rather confused than helped by a study of this part. This is unfortunate, as the polygraph is the more convenient instrument for clinical work in private, and if graphic methods are going to help the general practitioner it will be to it rather than to the electro-cardiograph that he will have to turn. The book has otherwise been prepared with care and with an appreciation of the beginner's difficulties. It is well produced and profusely illustrated. To one already acquainted with this class of work it will be of little value; to anyone about to take up this branch it will provide many useful hints.

The technique of cataract operation is a subject of perennial interest to ophthalmic surgeons, for the margin of success in methods is worthy of attention. Practitioners in India have overwhelming advantages in this respect, for the number of the cases they have to treat is beyond comparison with the relatively small number in countries of temperate climates. Colonel NEWMAN, I.M.S., has written a little book, *Irrigation in Cataract Extraction*, which, however, covers much more than the title would suggest. It is in fact a miniature monograph on the whole field of the operation. Mr. Newman's operation, for Mr. Newman of Belfast was a strenuous advocate of it, and his demonstration of cases will be remembered by those who attended the Belfast meeting of the Association some fourteen years ago. Others had tried the procedure, but he brought it into real prominence and demonstrated its value. The procedure has been in fashion and out of fashion more than once; the instrument makers' catalogues show some half a dozen patterns of nozzles employed by different surgeons, and Colonel Newman adds another to the number. His experience confirms that of other surgeons, which is that irrigation is of real value in many cataract extractions: first, in those where the operation has to be done for a senile nuclear cataract with unripe

*Heart Records, their Interpretation and Preparation*. By S. Carver Smith, M.S., M.D., Philadelphia. Philadelphia: F. A. Davis Company, 1922. (Pp. 270, pp. xiii + 132, 132 figures.) 7s. 6d.

FIG. 5.—The George Hotel, High Street.

At the top of High Street on the left are situated the Cambridge Barracks, first erected as stores during the Napoleonic wars. An enlargement of the barracks in 1856 necessitated the demolition of the old Portsmouth Theatre. This old building had many histrionic associations. Stephen Kemble was at one time its manager. Edmund Kean and Charles Kean were frequent visitors, and Dickens, in *Nicholas Nickleby*, makes it the home of Mr. Vincent Crummles's remarkable successes.

During the management of Stephen Kemble on one of the nights when there was no performance, a sailor off to India the next day asked to have the house opened that he might see a play before he sailed. An agreement was made and a tragedy was to be represented at a cost of five guineas, and no one to be admitted to the house except the sailor. *Richard the Third* was chosen for the presentation, and Kemble himself played Richard. The sailor thoroughly enjoyed the play, was perfectly satisfied, and cordially thanked the manager.

The house next the barracks, No. 10, High Street, was built on a demolished wing of No. 11, now called Buckingham House. The site of the old theatre was in the rear of these premises. The first house, where 10 and 11 now stand, was called "The Grehonde," and was occupied by the builder of Southsea Castle. When it was demolished, the next erected house was called the "Spotted Dog." In 1627 William Brooke had a licence for it as a "Comon Inne." Later it was occupied by John Mason.

Mason had been Governor of Newfoundland and in 1624 returned to England, but went abroad again in 1631, when he founded New Hampshire in America. On his return to England from this trip he was appointed Captain of Southsea Castle. When the Garrison Church was restored in 1874 the people of New Hampshire presented the gas standards, and a brass to Mason's memory was placed in the chancel. In 1628 the Duke of Buckingham was preparing his third expedition for the relief of Rochelle, and was a guest at Mason's house. He was unpopular in the country and with his own men. A certain Lieutenant John Felton, infected with the general dissatisfaction of the period and obsessed by a personal grievance at being refused promotion, bought a dagger on Tower Hill, and rode to Portsmouth, tethering his horse outside the town walls. The original entrance to Mason's house was under the round arch; a dark passage led to the central hall. In the passage Felton secreted himself on the morning of August 23rd, 1628. Buckingham breakfasted in a room off the dark passage, where he at the same time received a deputation from Rochelle. Breakfast finished, he was about to proceed to his carriage, but stopped for a moment to speak to Colonel Sir Thomas Fryer near the door of the breakfast room, when he was stabbed in the left breast by Felton. In a document found on the assassin he described himself "the heaven-sent avenger of his country's wrongs." He was tried, condemned to death, and executed at Tyburn, and his remains were gibbeted on Southsea beach, at a spot now marked by the boundary obelisk near Clarence Pier. The dagger used by Felton is in the possession of the Earl of Denbigh. The incidents of the murder have been dramatically used by Dumas in his novel *Les Trois Mousquetaires*.

On the opposite side of the road is High Street Chapel, a very old Nonconformist place of worship in Portsmouth. It was built in 1718, and has played a large part in the struggles for religious and civil liberty in the borough. Many noted men have been connected with it. In the graveyard attached to the chapel are the remains of the noble John Pounds; here also is buried Sir John Carter, nine times mayor of Portsmouth. Among the early ministers to the chapel was John Hicks, who was prosecuted several times for contravening the Conventicle Acts, and was finally executed for supporting Monmouth. Hicks, having escaped from Sedgemoor, was sheltered for one night by Lady Alice Lisle, at Moyles Court. She, although 71 years of age, was for this act the first victim of Jeffreys's assize.

A little further down High Street on the same side is a large house recently used as the headquarters of the Southern Command. It was prior to that the Governor's house, and its last occupant in that capacity was Prince Edward of Saxe-Weimar (1878-84).

Opposite is the famous George Hotel, whose history goes back to the time of James I. In those days it was a small thatched house with a water trough in front, and was known as the "Wagon and Lamb." At the end of the eighteenth century it reached the height of its glory, and was frequented by naval heroes, distinguished soldiers, statesmen, authors, poets, and even princes. The Duke of Wellington stayed here in 1814, but the "George" will ever be memorable as the house in which Nelson stayed for the last time in England. Mr. Saunders, in *The Annals of Portsmouth*, thus describes the occasion:

"Nelson arrived at 'The George Hotel' at six o'clock in the morning of the 14th September, 1805, rested and breakfasted; then observing that a great crowd was assembled in the High Street, stole secretly out of the back door in Penny Street. His retreat was soon discovered and the crowd rushed away, eager to see the face of the hero they venerated. They caught him upon Southsea Common, crowded round him, and struggled with each other to shake him by the hand. 'I wish I had two hands,' said he, 'and then I could accommodate more of you.' And the people cried, 'God bless you, Nelson.' There on Southsea beach, near the spot where the old *Victory's* anchor rests, Nelson embarked. As the boat pushed off from the shore the people ran into the water, once more to grasp that one hand of his and to wish him godspeed. . . . Thus that one eyed, one armed, pale, shrunken, invalid officer passed away from us never to return."

Our next object of interest is the Museum. It contains some interesting relics, models, drawings, and old engravings illustrating the history and antiquities of Portsmouth. The building itself has some architectural interest.

Medical Notes in Parliament.  
[FROM OUR PARLIAMENTARY CORRESPONDENT.]

| Year.     | Percentage. |
|-----------|-------------|

| Total. |             |               |                     |                       |              |

He said also that it was not considered desirable to issue a certificate of non-infectiousness from small-pox cases until they had been vaccinated. It was the function of the medical profession to see to it that no contagious diseases were introduced into the hospital or other offices, and he believed that the service of the medical officer would be best if he were to visit the patients in their homes.

—Mr. Chamberlain gave, on July 2nd figures as to benefits and costs of health insurance during the past three years:

time and space will not now permit a description of Thomas's Church, nor of the Garrison Church behind Grand Parade. Just before turning into the Grand Parade we pass the Soldiers' Institute. This building, we are told, came into the possession of Miss Robinson, was "Fountain Inn." Another inn—the "King's Arms" was also incorporated in the present establishment. On certain commemorations it was the custom for the house was much frequented by the tradesmen of the town. On certain commemorations it was the custom for the guests to give a dinner party, or as it was called a brick at the King's Head." The host marked account by having his initials, with the date, cut in one of the bricks forming the corner of the building. Edmund who visited this house during his engagements at the theatre, was, on the authority of Mr. Sandercock, one of those who "threw a brick at the King's Head."

Fig. 6-TLE CID Gold Hall.

peripheral layers, and again where fragments of lens are detached from the main cataract mass. In both types of cases washing out, under the strictest precautions of asepsis and gentleness of handling, shortens convalescence and reduces the density of after-cataract that may require needling.

Some have asserted that the procedure adds to the risks of the whole operation, especially from loss of vitreous. Newman gives his figures for 1,000 operations. Vitreous was lost on 38 occasions; 18 were primary—that is, before irrigation was attempted—and were caused by high intra-ocular tension, lid spasm, and dislocated lenses; twice it occurred without any apparent reason. Of the others, 10 followed the use of capsule forceps, and 9 the use of the irrigator; one was accidental.

The author's account of his own experiences of cataract operations in general is of much interest and distinctly stimulating.

### VITAMINS.

*Vitamins: A Critical Survey of the Theory of Accessory Food Factors* is a translation by EDEN and CEDAR PAUL of a volume written by Dr. Ragnar Berg, director of the laboratory of physiological chemistry at Weisse Hirsch. Our knowledge of vitamins is so recent and is expanding so rapidly that any large book on this subject must inevitably be partly out of date by the time it is completed. In the volume before us this disadvantage is aggravated by the extra delay due to the process of translation. In consequence it only gives an account of the work done to the beginning of 1922. The translators' preface of eight pages contains a rather unrestrained eulogy of the book. They claim that it marks the close of an epoch in that the author has summarized all the enormous mass of original literature dealing with vitamins within the compass of a single volume, and has provided a platform for the work of future investigators. It is true that anyone who endeavours to cope with the flood of vitamin literature deserves sympathy and praise, but to write of such a compilation as marking an epoch is to misapply that overworked phrase. The list of references it contains is fairly complete down to the end of 1921, but there are only half a dozen or so for 1922. Altogether there are 1,500 entries arranged in chronological order, but, unfortunately, the references for each year are not given alphabetically, and the ease with which the list can be consulted is thus greatly diminished.

The author himself states that the main aim of his book is to stimulate the study of the science of nutrition by Germans, and he will have done a great service to his countrymen if he succeeds in directing their attention to recent advances; their acquaintance with this field of knowledge has, he says, been handicapped by difficulties in obtaining access to foreign literature during and after the war. In his introduction he raises several objections to the word "vitamin" as a general term to cover the unknown accessory food factors, and suggests and uses the term "completin" instead of vitamin. Fortunately there is little fear of his example being generally followed; any such change in terminology at this stage could only lead to unnecessary confusion.

The book deals with the following main problems: the biological value of the various proteins; the importance of inorganic substances in nutrition; the various vitamins; and the deficiency diseases beri-beri, scurvy, malnutritional oedema, and pellagra. There is a chapter on the conditions of growth, and another on the importance of inorganic substances in nutrition, in which some interesting points are made concerning the absorption of calcium. We are unable to understand the statement, however, that potassium salts have a stimulating action on nerves and muscle (p. 81); it is true that they cause plain muscle to contract, but it is certain that they paralyse both nerves and cardiac muscle. There are good summaries of the knowledge of vitamins and deficiency diseases down to the date at which the book was written, and the chapter on

malnutritional oedema is of particular interest. The discussion on rickets is unsatisfactory since the importance of light in its prevention is not recognized. The reason for the omission is, of course, that the new facts were published during the past eighteen months. The discussion on the causation of pellagra is confused, as may be judged from the concluding statement (p. 322):

"Perhaps a lack of bases in general, and a deficiency of calcium and potassium in particular, in conjunction with an excess of acids and a lack of organically combined sulphur, might in course of time induce the nerve degenerations characteristic of pellagra, especially if the before-mentioned faults in the diet were supplemented by the inadequacy of the protein it contained, by deficiency in respect of A, B, and D, and maybe at times also by deficiency in respect of C."

This passage raises a further point: in its original state the text was doubtless excellent German, but in the process of translation it has ceased to be German and has scarcely become English. This criticism unfortunately applies to other passages in the book.

The author concludes by a plea for State aid in the study of the newer aspects of nutrition since large laboratories, extensive zoological gardens, and a large staff of analytical, biological, and anatomical experts are needed, and these conditions are difficult to attain in universities in Europe. He pleads for some organization to ensure that the general public is made aware of the facts.

"In addition to institutes for the biochemical study of nutrition there must be institutes of nutritive hygiene, whose task it will be to ensure the practical application of the theoretical acquisitions of biochemistry, to ensure that the data of the new science of nutrition shall be realized in daily life. The consciousness of the masses must be permeated with a practical knowledge of the new science of dietetics."

This plea is undoubtedly sound, for there is every reason to believe that the effects of partial vitamin deficiency prolonged over several generations may very seriously affect the health of modern urban communities.

In conclusion it may be said that Dr. Berg has written an interesting general account of deficiency diseases, which, however, for the reasons we have suggested, is not completely up to date, but he expresses some ideas of his own on the subject of inorganic metabolism which are interesting, although in some instances they have not met with general acceptance.

### SURGERY OF THE HEAD AND NECK.

THE book on the surgery of the head and neck by LENORMAND and BROCC<sup>2</sup> is one of a series prepared by the Prosectors of the Faculty of Medicine in Paris, and intended for students preparing for examinations and for practitioners who, while they may be unable to obtain access to the larger works on surgery, are anxious to keep up to date. The volume under review is excellent. There is, as far as we know, nothing exactly like it in English. The size is convenient, the type large and clear, and the illustrations numerous and good.

In spite of its rather wider title, the volume is actually limited to operative procedures, but with this qualification we cannot speak too highly of the text. Each section is introduced by a clear description of the topographical and the deep anatomy of the part under consideration. After this, the indications which demand operative interference are discussed. As a rule only one method of operating is described, and we presume it is that which is followed in the practice of the authors; each stage of the operation is illustrated by helpful line drawings. The after-treatment also is fully considered. Certain operations have been included which would seem unnecessary, such, for example, as hemilaryngectomy and resection of the cervical sympathetics.

One criticism of the illustration work is demanded. In indicating the lines of excision of malignant tissue the incisions are shown dangerously close to the tumour. No doubt such an error would never arise in the authors' practice; but, if the volume is to be put into the hands of

<sup>1</sup> *Vitamins: A Critical Survey of the Theory of Accessory Food Factors.* By Ragnar Berg. Translated from the German by Eden and Cedar Paul. London: George Allen and Unwin, Ltd. 1923. (Demy 8vo, pp. 415. 18s. net.)

<sup>2</sup> *Chirurgie de la Tête et du Cou.* By Ch. Lenormand and Pierre Brocq. Sixth edition. Paris: Masson et Cie. 1923. (Double cr. 16mo, pp. 338; 245 figures. Paper. fr. 10; bound. fr. 12.)

students and practitioners, a harmful impression may be conveyed. Apart from these criticisms the volume has impressed us as being a most valuable contribution to the "teaching" class of operative surgery literature.

### NOTES ON BOOKS.

It was fortunate that when the aged tortoise at the Zoo was in a retrospective frame of mind his confidences were received by two such capable historians as Mr. KENNETH WALKER, F.R.C.S., and Mr. GEOFFREY BOURMIREY, who have thus been able to give to the world a true and faithful account, with many spirited pictures, of the behaviour of the animals in the ark during the distressing days of the flood. Through the courtesy of the aged tortoise they were directed to a cave in Armenia where long-forgotten records were concealed and where pictures were discovered which have been reproduced to illustrate *The Log of the Ark*.<sup>6</sup> It appears that life was very pleasant in the ark when the weather was fine, but the discomforts and anxieties were considerable during the period of heavy rain. Moreover, the happy harmony which it has always been assumed existed between all the voyagers in this remarkable vessel was, as the authors have shown, more apparent than real, for the wicked machinations of the scub introduced an atmosphere of distrust which added greatly to Noah's difficulties and almost resulted in disaster. This is a book for all children between the ages of five and ninety-five. Opponents of the higher criticism of the Book of Genesis could say nothing more censorious than that the *Log of the Ark* represents fiction founded on fact. It is an amusing and captivating tale, written in an original vein, and such as we all enjoy at this season of the year.

The *British Journal Photographic Almanac* for 1924, the sixty-third issue, is again edited by Mr. GEORGE E. BROWN, and is on similar lines to those immediately preceding it. All things photographic are dealt with in this yearly publication, and the extensive advertisements cover practically everything which is used by photographers, either amateurs or professionals. These advertisements use up some 458 pages out of the 811 of the book, and the illustrations are numerous and excellent. An article on using a hand-camera by the editor should be of especial value to that numerous band of amateurs who confine themselves to snapshot photography, who for the most part do not trouble to make themselves acquainted with even the rudiments of the art, and have practically no knowledge of the limitations of this form of photography. There is an enormous amount of information upon such subjects as colour photography, printing processes, negative processes, photographic formulae, and so on; the result is that as a reference book it is invaluable.

A short but instructive book on the *Principles of Home Nursing*,<sup>7</sup> by EMMA L. MOHS, describes in simple language and accurate scientific detail how nearly a home nurse can approximate to the efficiency of a modern hospital nurse. Part I is devoted to sick-room nursing and gives information on home substitutes, chart keeping, and diets. Part II deals with emergencies and first aid. Part III has a well written chapter on reproduction and describes maternity nursing and the care of the infant. A short list of reference books on sex, heredity, and eugenics is included. Part IV explains bacteriology and immunization. There is a bibliography and a glossary.

### MEDICINAL AND DIETETIC PREPARATIONS.

#### A Dietetic Toast Biscuit.

The preparation of articles of diet, perhaps the oldest of domestic sciences, has its settled rules. They have a certain affinity with those governing pharmaceutical operations, but pharmacy has not usually been applied to dietetics except in the production of medicated foods. These have seldom attained any degree of popularity; there is a natural aversion from medicine at a feast; but there is no reason why the preparation of ordinary food with pharmaceutical acumen and understanding, should not succeed both in the excellence of the product and a gain of public favour. Messrs. Macfarlane Lang and Co. have introduced a "Dinner Toast" biscuit manufactured in this sense for the use of persons with whom ordinary bread disagrees. A sample has been submitted to our analyst, who reports that it contains no medicament and no unusual baking constituent. The analytical examination agrees with the manufacturers' statement that the biscuits are made only from the finest wheat flour with pure butter, malt, and milk. They were found highly palatable.

### THE IMPERIAL CANCER RESEARCH FUND.

#### SCIENTIFIC REPORT.

The eighth Scientific Report of the Imperial Cancer Research Fund which has just been issued<sup>1</sup> maintains the high standard of excellence that we are accustomed to look for in the publications of that institute. Some of the articles included in it have already appeared in journals during the two years that have elapsed since the last report: the majority of the papers are now published for the first time. As usual, the researches have been pursued along various lines with commendable thoroughness.

#### Carbohydrate Metabolism of Normal and Cancerous Tissues.

The first two papers are devoted to a consideration of the carbohydrate metabolism of surviving normal tissues and of tumours. This work of Dr. B. R. G. Russell, which is a continuation of previous studies on the metabolic exchanges of tissues, is of very great importance, for it is only by such means that we can hope to lay the foundations for a rational chemotherapy. In the first of the two papers certain normal mouse tissues were contrasted with different strains of transplantable tumours with regard to their powers of oxidizing glucose and other common carbohydrates supplied to them directly; no striking differences could be detected between the two classes, although tumours growing at different rates manifested variations in their carbohydrate metabolism. In the second paper, however, Dr. Russell relates how he succeeded in demonstrating distinct differences between normal and malignant tissues in their metabolism of pentoses. It was found that mouse tumour tissue had the power of consuming rhamnose, xylose, and arabinose, a property not possessed by any of the normal tissues investigated with the single exception of liver tissue, which could attack arabinose. To one unfamiliar with the technique employed it may seem that the magnitude of the changes recorded is small, and, as Dr. Russell himself suggests, it may not be safe to argue from phenomena observed in surviving tissues to what might occur in tissues in full activity; but still we have here for the first time an indication of a difference in metabolic properties which we may trust the author and his colleagues to explore thoroughly with the knowledge that everyone interested will wish them success.

#### Vitamins and Cancer.

Dr. W. Cramer's paper on dietary deficiencies and the growth of cancer is a thoughtful and original contribution to our knowledge of vitamins. His experiments with vitamin-deficient diets support the findings of Drummond and, being carried further, prove practically beyond a doubt that the growth of malignant tumours does not depend on the presence of the accessory food factors. It has hitherto been accepted, almost without question, that vitamins are essential for the growth of normal cells. If this were true it would denote a fundamental biological difference between the factors controlling the growth of normal cells and of cancerous cells, seeing that tumours grow just as well in animals deprived of vitamins as in the normal controls. But Dr. Cramer's investigations have led him to reject the popularly accepted opinion. He points out that there is a considerable gap between the observed facts and the generalization that every cell requires vitamins for its life and growth, and he shows that the atrophy resulting from a vitamin-deficient diet affects very specifically certain tissues or groups of cells, and further that deficiency in one vitamin affects one specific tissue, whilst deficiency in another affects an entirely different group of cells. Thus, absence of vitamin B leads to an atrophy of lymphoid tissue with consequent lymphopenia, and absence of vitamin A is followed by an atrophy of the intestinal mucosa, the other tissues showing no corresponding primary change, some of them indeed—for instance, the adrenal—actually undergoing hypertrophy. He compares this with analogous results following a diet deficient in tryptophane, in which case also transplanted tumours will go on growing. His conclusion seems reasonable, that the absence of vitamins affects certain tissues without which the whole animal cannot live.

There is no reason to believe that an abundant supply of vitamins in the food may be harmful to patients suffering from cancer, or, on the other hand, that the withholding of these could retard the progress of the growth. There are several other interesting considerations in this communication which will repay study: suffice it to say that the whole paper is a brilliant piece of constructive criticism.

#### *Cultivation of Tissues.*

Dr. A. H. Drew contributes two valuable papers on the cultivation of tissues *in vitro*, the first dealing with the conditions essential for the continued growth and differentiation of normal and tumour cells, and the second with an analysis of the growth-promoting factors. These substances have been found in much greater abundance in embryonic than in normal adult tissues and they are capable of passing through a Berkefeld filter. Autolysed extracts of normal adult tissues contain a similar growth-activating substance, while ice-cold extracts of tumours, not autolysed, yield it readily. It would appear that malignant tumour cells continuously form this substance. The observations are of prime importance and their significance will be readily appreciated.

#### *Tar Tumours.*

Dr. A. M. Begg, in a histological study of 140 tar tumours in mice, gives an interesting account of the modes of dissemination of these epitheliomatous growths. Several showed definite invasion of lymphatics and blood vessels, and no less than 18.5 per cent. gave evidence of spread along the perineurium of nerves. Doubtless this number would have been higher had serial sections been examined from each case. This mode of extension by nerves is rare, though not unknown in human cancer. Dr. Begg brings out the curious fact that in the mouse there is apparently a strongly specific tendency for malignant squamous epithelial cells to travel in this way, even in the case of transplants from the original cutaneous tumour. Other growths, such as adeno-carcinoma of the mamma, do not show this peculiarity.

Hitherto all attempts have failed to induce tumour growths of the skin of rats by tar or any of the other means that have proved successful in mice and rabbits. Dr. Russell has, however, been able to produce sarcoma in rats by weekly subcutaneous injections of tar over a long period. In one instance it took eleven months before there was any sign of growth, and in another case eighteen months, the injections in the latter case having been suspended at the end of a year. But once the tumour has started the development of the sarcoma is rapid. Dr. Russell holds that the neoplastic reaction is quite suddenly declared, as nothing in the way of any special preparatory phenomena can be detected histologically before the development of frank sarcoma. Although in the case of tar epitheliomata in mice a stage of simple wart formation is generally seen, there are some grounds there also for believing that the transition to malignancy is abrupt.

#### *Resistance to Cancer.*

The Director, Dr. J. A. Murray, discusses the questions of primary and secondary resistance to the induction of cancer. No adequate summary of his authoritative paper can be given here, as it is already so condensed. Refraining as much as possible from speculation, he brings into relationship the observations made on the experimental production of cancer by irritants and the observations of Drew already mentioned. "A certain amount of activating substance is probably produced by any kind of cell damage, and when by constant repetition this production has become automatic, proliferation will continue after the removal of the initial cause of protoplasmic disintegration. Temporary hypertrophies would, in this conception, correspond to the purely reactive production of activator, ceasing when the irritant is removed, benign growth to an autonomous production in small amount, and malignant growth to a more abundant production." According to this view the irritant does not produce its result by gradually breaking down the resistance of the economy to the unrestricted powers of growth of its constituent cells, but the cell acquires new properties or exaggerations of its normal activities which act disastrously to the rest of the organism. Dr. Murray

develops further his thesis that the formation of one malignant tumour protects the individual permanently, or at any rate for a long time, against the development of a second primary tumour. The importance of these experiments lies in the indication they give "of a systemic constitutional change in the organism in which cancer has developed, a change which, if it could be recognized with certainty and rapidity, would enable us to recognize cancer in its earliest stages, and could we produce it without initiating new growth, would place in our hands a rational means of prevention." The reviewer, although impressed by the facts on which this conclusion is based, cannot wholly subscribe to the inferences so persuasively drawn; but, however that be, the experimental facts conclusively show that there is no constitutional liability to the development of cancer.

#### *Paraffin Dermatoses.*

The report ends with a detailed account of the occupation dermatoses of the paraffin workers of the Scottish shale industry by Dr. Alexander Scott of Broxburn. It may be remembered that Dr. Scott contributed briefly his observations on these precancerous and epitheliomatous lesions at the Annual Meeting of the British Medical Association at Glasgow in 1922,<sup>2</sup> and we expressed a hope that he might give a more exhaustive communication than is possible in the pages of a medical journal. We are therefore glad to see that the Executive Committee of the Imperial Cancer Research Fund has afforded him the opportunity of recording "the results of an unintentional experiment on a large scale in the human subject, carefully observed and recorded over a long period. As the same favourable conjunction of material and observer is unlikely to recur, it was deemed advisable to make an adequate permanent record of it widely available." This is a merited compliment to both parties.

It would be idle to pretend that organized cancer research in this country has escaped adverse criticism at the hands of some publicists who apparently have neither watched its development attentively nor perceived the gradual unfolding of its objectives; to all such and to the impatient this report should be an effective reply.

### ROYAL MEDICAL BENEVOLENT FUND.

At the last meeting of the Committee thirty cases were considered and £350 voted to twenty-two applicants. The following is a summary of some of the cases relieved:

Daughter, aged 77, of M.R.C.S. who died in 1878. She had been given a home and an allowance of £26 a year for some years by a cousin who died last May. Voted £26 in twelve instalments.

Daughter, aged 39, of M.R.C.S. who died in 1902; has supported herself as a governess. Her expenses during six months' unemployment were about £52, and her total income about £70. She asked for temporary assistance. Voted £10.

M.R.C.S., aged 60, who had to give up practice in 1892. Down to 1921 applicant's board, lodging, and attendance were paid out of his annuity, supplemented by friends' gifts and help from a brother who is now unable to continue it. The Committee voted £26 in twelve instalments for the third time.

Daughter, aged 70, of M.R.C.S. who died in 1870. Owing to chronic ill health applicant is unable to support herself. She lives with an old nurse and pays 3s. 6d. a week rent. Her only income is £20 from the Home for Incurables and the Old Age Pension. Voted £10 in two instalments.

Subscriptions may be sent to the Honorary Treasurer, Sir Charters Symonds, K.B.E., C.B., M.S., at 11, Chandos Street, Cavendish Square, London, W.1. The Royal Medical Benevolent Fund Guild still receives many applications for clothing, especially for coats and skirts for ladies and girls holding secretarial posts, and suits for working boys. The Guild appeals for second-hand clothes and household articles. The gifts should be sent to the Secretary of the Guild, 43, Bolsover Street, W.1.

<sup>2</sup> BRITISH MEDICAL JOURNAL, August 26th, 1922, p. 381.

THE third number of the *Bibliography of Industrial Hygiene*, published by the International Labour Bureau at Geneva last September, contains a list of cinematograph films, of which a collection is being made. They will be classified under six headings: general conditions of life and work, agriculture, industry, commerce, emigration, and films for school use. In the present issue only some parts of the first heading are dealt with. The number also includes a list of 468 publications dealing with industrial hygiene which appeared during the preceding twelve months.

SATURDAY, DECEMBER 22ND, 1923.

## SLEEP.

"Happy is the man that findeth wisdom; his sleep shall be sweet."

The immortals never slept. This we have on the authority of Mr. Bernard Shaw, and we are left to infer that a periodical retirement for recuperative purposes is the diseased product of a physical civilization. It would appear, therefore, that Methuselah and his kin had by one grand elevation of intellect—not unassociated, we suspect, with the discipline of a vegetarian dietary—divorced themselves from all affinities with the larger animal world. It may be that our inimitable dramatist is here making witting exposition of the physiological inability to fatigue nerve tissue, but more probably we are expected to concede that conceptions of the flesh are beside the point in a psychological dissection of the superman.

However this may be, the picture of an un-sleeping immortality is not such as to commend itself to the aspirations of the human kind. The philosophy of every age has evinced a lively preoccupation with "Sleep, the lesser mysteries of Death." Whilst in the pagan mind is found all the child's terror of the mysteries of the night—

"The children twain of dusky night,  
The dread gods Sleep and Death"

—religions have found in sleep that rest and peace which is to be the guerdon of the faithful. The Oriental, seeking a perpetual sleep in Nirvana, makes common purpose with the Greek idea, which, conceived the highest development of intelligence to be a negation of consciousness. From the nation which sought a final rest on the bosom of Abraham arose the faith which assured that "He giveth His beloved sleep." For all his terror of the unknown, man has found no greater serenity than to yield to the seductive wooing of "queenly sleep," and has known no heavier punishment than that which Nature yields when she withholds sleep from the uneasy conscience or the uneasy body. As with Lady Macbeth, so with Brutus—"Since Cassius once did whet me against Caesar, I have not slept." Neither philosopher nor poet would seek to steal from us our bed.

"Not of the Mortals sleep, nor of the Immortals,  
But blended of the twain."

Physiology has had little to add to the understanding of either the balm or the terror of sleep. We are at pains to prescribe the minimum requirement for child or for adult, while we cannot yet say wherein sleep is the "dear mother of fresh thoughts and joyous health." Medicine, whose chief handmaid is sleep, stands helpless by whilst the greater mystery snatches the life even from the arms of sleep. Professor MacWilliam, in a contribution printed at page 1196, brings to this problem criticism and suggestions which will seriously engage attention. He is disposed to question the comfortable view that sleep is a convenient degree of cerebral anaemia. The frequent occurrence of haemorrhage—cerebral, pulmonary, and gastro-intestinal—at night argues against a general

reduction in blood pressure in these cases. Professor MacWilliam has previously suggested that sudden death by night may be due frequently to fibrillation of the ventricles of a debilitated heart, and now questions why this should occur and why anginal attacks should be common under the leisurely circulatory conditions reputed to obtain in sleep.

While it must be generally conceded that in deep undisturbed sleep there is a reduced blood pressure, a modified vascularity of the brain, and a depression of metabolism, respiration, and reflexes, it is suggested that in the uneasy sleep associated with dreams and nightmares a very different complex may be presented. The author discusses the evidence that such disturbed sleep may be associated with an elevated blood pressure, with pulmonary irregularity, with an augmented cardiac impulse, or with exaggeration of the lower reflexes. If such be of general occurrence it is not difficult to associate drastic lesions of the heart or vessels with their onset. It is suggested, indeed, that measurements of these circulatory disturbances which were made at the moment of waking from restless sleep pointed to a condition of stress exceeding that which was found in the same subject after indulgence in a short bout of moderate exercise. In Burton's *Anatomy of Melancholy* we find Lemnius quoted that uneasy sleep "causes dryness of the brain, frenzy, dotage, and makes the body dry, lean, and ugly to behold. The temperature of the brain is interrupted by it, the humours adust, choler increased, and the whole body inflamed." The great Galen himself writes that some sleep "overthrows the natural heat, causes crudities, hurts concoctions." Can we yet explain these observations?

While Professor MacWilliam leaves untouched the larger question of the cause of sleep, he is evidently inclined to suggest that the reduced blood pressure is an effect rather than a cause of sleep, or rather that the effect of sleep upon the circulation depends on the depth and the nature of the sleep. Although the crude analogy with anaesthesia cannot be upheld, it is significant that exaggeration or depression of the response of the lower centres follows the depth of anaesthesia.

Some readers may have had the privilege of hearing the address delivered to the International Congress of Physiology by Professor Pavlov last July. It is unfortunate that the remarkable studies of the Russian school on the physiology of the cortex are not yet available in any but the Russian tongue, and till this may be rectified the conception of conditioned reflexes and all that this implies will hardly achieve general recognition. In the address referred to<sup>1</sup> Professor Pavlov afforded some indication of the extension of these studies to the physiology of sleep, which gives the subject an entirely new orientation. Readers familiar with this school of thought need not be reminded that the cortex is held to be the seat of two contending activities—excitation and inhibition. A single "voluntary" action—the whole behaviour of the individual, indeed—is the expression of a balance between these two contending activities. The Anglo-Saxon differs from the Latin in the relative predominance of his inhibitory functions, and it may be a matter of some satisfaction to the northerner, therefore, that this does not imply a relative mental passivity, since inhibition is to be regarded as a process as positive as is excitation. Sleep, on this basis, becomes a spontaneous irradiation of inhibition over the cortex. The spreading may be to a greater or

lesser extent complete, corresponding to a varying quiescence of the higher centres. Associated with incomplete irradiation of inhibition must be found areas of excitability, and these by induction are regarded as being hyperexcitable. Under such conditions it does not seem difficult to believe that minor sensory or other stimuli falling on the active areas may give rise to exaggerated responses and by invasion of the inhibited territory may arouse the whole cortex to excitability and awaken the individual. This much seems established. On the other hand, one conceives that minor stimuli may fail to awaken the sleeper, but, falling on excitable areas, may be transmitted to the lower centres to give just those extravagant responses which are to be found in disturbed sleep as described by Professor MacWilliam.

The outlook is fascinating in the extreme. To be able to look upon sleep as a positive active process is a real advance. The circulatory and other changes associated with the sleeping condition then become clearly effects rather than predetermining causes. Why do we "go" to sleep? What determines the initial irradiation of inhibition? This question remains to be answered. Is it itself a time-conditioned reflex? For all our conjecture he is still a fortunate man who can exclaim with Sancho Panza: "Only I know that whilst I am sleeping I neither fear nor hope, have neither pain nor pleasure; and well fare the man that invented sleep."

### THE VIRUS OF THE COMMON COLD.

THE infective diseases of unsolved etiology are a field in which new knowledge is being sought actively to-day on every side and in many countries. To judge by the daily press, the general public takes almost as much interest in this branch of progress as the medical profession. We like to think that this popular interest is the outcome, not of mere curiosity, but of a wide appreciation of the fact that each new piece of knowledge, even when it has no immediate practical application, promises to bring us a step nearer to the time when the control and treatment of these diseases shall be far more efficient than is at present possible.

An endemic disorder of this category, of minor significance it is true, but for all that a prominent pest of modern town life, is the common infectious cold. Although for obvious reasons excluded from the list of notifiable infections, this malady from time to time during the winter months makes its appearance, and, by spreading through the town apparently unchecked until it has exhausted the susceptible material, acquires the proportions of a minor pathological scandal. Excluding the part it often plays as the precursor of respiratory maladies of graver import, the common cold must cause annually in the aggregate a vast amount of inconvenience, depression, irritability, and loss of working efficacy, none the less real because this disease has not yet acquired the dignity of official recognition. A further feature of the common cold is the comparative brevity of the acquired immunity that follows on an attack. Thus many people suffer regularly once a year, while some have two or more attacks, and those unfortunate individuals when they are enjoying a temporary respite and come by chance in contact with a person in the acute explosive stage of a cold know by repeated experience that their chance of escape is but small.

It would seem that the pathogenic agent responsible for the common cold has not yet been established beyond dispute. Thus while a number of well known

bacteria, generally designated "catarrh organisms," occur in the respiratory discharges in catarrhal conditions of all sorts, and undoubtedly play an important part in the later stages of the common cold, it has been suspected for some time past that this malady is due primarily to some more elusive pathogenic agent; in short to some special principle *sui generis*. In favour of this view is the circumstance emphasized by Foster that during the earliest stage of the attack of a common cold the nasal secretion is clear and remarkably free from bacteria of any kind when examined by the usual methods.

Since the common infectious cold is especially a disease of the human subject it was always probable that its etiology would be solved in the end by human experiment. The earliest observations on these lines appear to have been made in 1914 by Kruse,<sup>1</sup> who succeeded in transmitting colds by instilling into the nares of volunteers the diluted nasal secretion of an acute case after filtering it free of ordinary bacteria. In 1917 Colonel George Foster<sup>2</sup> of the United States Medical Corps repeated and confirmed Kruse's observation in some carefully controlled experiments on volunteers from an isolated garrison of soldiers, and succeeded in transmitting the disease, not only with filtered nasal secretion, but also with a culture in Noguchi medium obtained by inoculation with this filtered secretion. Foster, moreover, found some very minute "globoid bodies" in his cultures which he looked upon as probably the infective agent.

The latest contribution comes from the Rockefeller Institute, where Olitsky and McCartney<sup>3</sup> have carried out some experiments on volunteers with the filtered naso-pharyngeal washings in a number of cases in the acute stage of the common cold. In six separate instances where the secretion was taken before the eighteenth hour from the onset, transmission of the disease was effected by gently rubbing a swab charged with the filtrate on the nasal mucosa. Control experiments with the same material heated to 60° C. gave negative results. The incubation period varied from eight to forty-eight hours. In two further cases in which filtered naso-pharyngeal secretion taken after the eighteenth hour from the onset was inoculated, the results were negative. Cultures of the filtered naso-pharyngeal secretion in Noguchi medium, and also in anaerobic blood-agar plates, failed to yield either the globoid bodies seen by Foster or the minute organism *Bacterium pneumosintes* found by Olitsky and Gates in similar cultures in cases of influenza. While several minute anaerobic organisms were cultivated, no organism was found that could be especially identified with the common cold. Experiments on rabbits with the naso-pharyngeal secretion from these cases of colds failed to produce the results obtained with similar material taken from cases of influenza.

These experiments, therefore, suggest that the active principle of the common cold belongs to the group of filter-passing viruses, and that the precise nature of the pathogenic agent here involved has still to be determined.

SIR CHARLES SHERRINGTON, Waynflete Professor of Physiology in the University of Oxford, and President of the Royal Society, has been elected a corresponding member of the Section of Medicine and Surgery of the Académie des Sciences, Paris, in succession to the late Sir Patrick Manson.

## ROCKEFELLER GIFT TO EDINBURGH UNIVERSITY.

THE University of Edinburgh has received from the trustees of the Rockefeller Foundation an offer of a capital sum of £50,000 for the erection of a clinical laboratory in conjunction with the Royal Infirmary, and for the completion of the endowment of the professorship of surgery on a full-time basis. The trustees have offered also an annual grant of £1,750 for five years, from which certain salary charges in clinical medicine and clinical surgery could be met. The offer was formally received by the University Court on December 17th, and negotiations will no doubt at once be opened with the managers of the Royal Infirmary. It will, we understand, be necessary for them to obtain more ground: they are already committed to a new x-ray department and other extensions of the infirmary, for which they hope to get ground in the neighbourhood. The erection of a clinical laboratory such as the Rockefeller trustees contemplate will, it seems obvious, make it necessary to obtain still more ground. There is also the question of a site for the new maternity hospital, which some desire should be in the immediate neighbourhood of the infirmary. We have no doubt that the difficulties will be overcome, for Edinburgh will not lightly lose such an addition to the teaching facilities of its medical faculty as is now made possible. This is the third great gift made by the Rockefeller Foundation for the advancement of medical education and research in Great Britain; the other two are the gift for the erection of the Imperial School of Hygiene in London and the grants made to University College, London, for the erection of the Institute of Anatomy, for additions to the staff of that department and certain others, and to University College Hospital and University College Hospital Medical School for the extension and perfecting of the facilities they afford for medical education, so that they may become an ideal medical school in London, equipped in all departments on the most modern lines. It was only last week that the Rockefeller trustees announced that they had granted one million dollars (£200,000) as an endowment for the maintenance of the medical faculty of Toronto University. For the last three years the University has enjoyed the income derived from this amount; the capital sum is now definitely handed over to it. The gift is made in recognition of the research work done by the medical faculty, culminating in the discovery of insulin.

## SIR WILLIAM MACEWEN IN AUSTRALASIA.

THE boat on which Sir William Macewen sailed from San Francisco to Sydney on his way to the Australasian Medical Congress of the British Medical Association at Melbourne touched at Wellington, New Zealand, on October 10th, when Sir William, who was accompanied by his son, Dr. William Macewen, was welcomed by members of the New Zealand Branch. The boat arrived on October 15th at Sydney, where he was to have been entertained by Sir Walter Davidson, Governor of New South Wales, but that distinguished public servant had died on September 16th. On October 19th the students of the Sydney University Medical Society offered Sir William Macewen an official welcome in the great hall of the University; addresses were given by Dr. R. A. Money, president of the society, Professor A. E. Mills, dean of the faculty of medicine, and Professor F. P. Sandes, professor of surgery. After Sir William had replied the first verse of the 'Varsity anthem was sung, and the meeting, which was attended by some 300 persons, resolved itself into a conversazione. On October 22nd he was entertained at dinner by the Glasgow University medical graduates. On October 25th, at a special meeting of the senate of the University of Sydney, the degree of M.D. (*ad eundem gradum*) was conferred upon him; the Chancellor, Sir William Cullen, K.C.M.G., presided, and

there was a large attendance of members of the senate, of the professorial board, and of the profession. In introducing Sir William Macewen to the Chancellor Professor Mills, who is a member of the Council of the New South Wales Branch, sketched the eminent career of the new graduate and described the value of his contributions to science. Afterwards he was entertained at lunch in the Fisher Refectory of the University by the Warden and Registrar, Mr. H. E. Barff, M.A., C.M.G. On the same evening the New South Wales Branch gave a dinner in his honour, which was attended by some 101 members and by a number of guests, including the Premier of New South Wales, Sir George Fuller, K.C.M.G. On the following evening (October 26th) Sir William attended a meeting of the New South Wales Branch in the Anatomy Department of the University, when an address on a new operative procedure in the treatment of spastic paralysis and its experimental basis was given by Dr. N. D. Royle; it was illustrated by demonstrations on experimental animals and on the living man, and by moving pictures and lantern slides. Professor J. I. Hunter also gave an address, on the tonic influence of the sympathetic nervous system. Dr. C. H. E. Lawes, President of the Branch, both at the dinner and at the meeting expressed the satisfaction of the members in having among them Sir William Macewen, with whose name and work they were so familiar, and the gratification felt in the honour done to them by the Association in arranging that so distinguished a member of the profession should represent the Association at the Australasian Medical Congress in Melbourne, the first to be held under the auspices of the Branches in Australia. The State Government invited Sir William to make a tour as its guest, but time only permitted him to visit the wonderful and beautiful Jenolan Caves; to reach them he travelled by a car placed at his disposal by the Government through the Blue Mountains, a two days' trip there and back. As he was due at Melbourne on November 12th he was unable to accept an invitation from the Queensland Branch to visit Brisbane. The Congress was to begin in Melbourne on November 12th under the presidency of Dr. G. A. Syme, and we have made arrangements to publish an account of its proceedings as soon as it reaches this country.

## CONGRESS OF THE BELGIAN CANCER LEAGUE.

A CONGRESS was held in Brussels from November 18th to 21st, under the presidency of Professor Depage, with the object of instituting the Ligue Nationale Belge contre le Cancer. It is apparent from the many lectures and demonstrations that the Ligue considers the most promising line of treatment to be by irradiation. With this belief, a great number of demonstrations of the exact technique for the use of radium and x rays had been arranged, and a considerable number of patients who had been treated by this method were collected. Of particular interest was the technique employed in the gynaecological cases, and it is specially to be noted that the gynaecologists associated with this work have given up entirely the use of Wertheim's hysterectomy for carcinoma of the cervix. Their present method of treating this condition is, briefly, as follows. First radium is applied in the vagina, by means of needles and tubes, for at least six days; a month later radium is placed in the pelvis through an abdominal incision, and left for at least six days; another month later the patient is treated by means of deep x-ray therapy. The Radium Institute in Brussels has only recently been founded, and therefore it is too early to say anything about final results, but it is possible to observe that those at the end of one year are truly remarkable. It is interesting to contrast the treatment carried out at this institute with that of the Radium Institute of Paris, where surgical procedures for

the application of radium are avoided as much as possible. The institutes have, however, one point in common—the workers at both believe that a moderate dose given over a long time, such as a week, is of greater value than a large dose given for a short time, say twenty-four hours. Other demonstrations included the treatment of carcinoma of the rectum by needles buried in the tissue around the growth, and of malignant disease in many other parts of the body, such as the tongue and breast. A somewhat novel technique for x-ray therapy of the breast is being employed by Dr. Sluys, who is burying a number of gold needles in the form of a gridiron in and around the growth while irradiating the tumour. The needles, of course, give off a number of secondary irradiations, which it is claimed intensify to a very marked degree the action of the rays. During the congress the evenings were occupied by gatherings of a social character.

#### PARASITOLOGY IN EGYPT.

IN keeping with recent diplomatic pronouncements, there is taking place in Egypt a gradual replacement of European officials by those of Egyptian nationality. The ultimate success or failure of this policy will profoundly affect the well-being of the country, and in no department to a greater degree than in that of the public health. For several years past the Egyptian Educational Mission has pursued the enlightened policy of sending the most promising of the senior students of the law and medical schools to Europe for several years of post-graduate study, and has thus provided a personnel, trained at least from the academic side, from which appointments can be made. We are glad to learn that the Minister of Education has recently taken a step which, looking to the future needs of Egypt, is one which reveals a far-seeing statesmanship. Dr. Mohammed Khalil has been appointed subdirector of investigations in ankylostomiasis and bilharziasis in the Public Health Department. In order that the duties of conducting researches on the important endemic parasitic diseases may be adequately carried out in relation to the practical problems in the field, facilities as to material and for clinical observation have been assured by the allocation of six beds, which will be under the charge of the subdirector, in the large Kasr-el-Aini Hospital in Cairo. Another important step in this co-ordination of parasitological work is the appointment of the subdirector as lecturer on parasitology at the Cairo Medical School. It is to be hoped that the Veterinary and Agricultural Schools will be brought ultimately into the scheme, for the interrelation of the helminth parasites which affect man, the domesticated animals, and plants is very intimate, and any systematic attempt to study the one cannot omit to deal with the others. Dr. Khalil is to be congratulated on the well deserved recognition which the Egyptian Government has thus given to his contributions to helminthological research. An historic mantle falls upon his shoulders, for the land of Egypt is the home of helminthology, and has already been the happy hunting ground of Bilharz, Sinsino, Looss, and Leiper. As an undergraduate in medicine Dr. Khalil was a student of Professor Looss, and for some years after graduating he was a member of the group of research workers associated with Professor Leiper at the London School of Tropical Medicine, and during that period visited British Guiana as a member of the Filariasis Commission.

#### PARENTS' RESPONSIBILITY FOR MEDICAL TREATMENT.

THE conviction at the Old Bailey on December 14th of Henry Norman Purkiss and Louisa Purkiss, members of a religious sect called the "Peculiar People," of the manslaughter of their son, aged 3 years and 3 months, by

neglecting to call in medical aid when the child was suffering from diphtheria, serves as a reminder of a question dealing with the mental element in crime which remained unsettled until statute came to the aid of the common law. In such cases of parental neglect to seek medical aid a conviction was not always obtained, as was shown by the case *R. v. Wagstaffe* (1868), 10 Cox, 530, chiefly because of the application of the old common law maxim, "Actus non facit reum nisi mens sit rea"—that there cannot be a criminal act without a criminal mind. This maxim applied with especial appropriateness to the members of the sect of "Peculiar People," of whom there are 2,000, chiefly confined to Essex, whose faith forbade the seeking of medical aid on the ground of the text: "Is any sick among you? let him call for the elders of the church; and let them pray over him, anointing him with oil in the name of the Lord: and the prayer of faith shall save the sick, and the Lord shall raise him up; and if he have committed sins, they shall be forgiven him" (*Jas. v.*, 14, 15). A short time after the decision in *R. v. Wagstaffe* the Legislature included a provision in the Poor Law Amendment Act, 1868, designed to meet such cases—"When any parent shall wilfully neglect to provide . . . medical aid"; and it was upon this express statement of the law that a conviction was secured in *R. v. Downes* (1875), 1 Q.B.D., 25. The Prevention of Cruelty to Children Act, 1894, omitted to restate this provision regarding medical aid, merely saying, "wilfully neglects such child," and in *R. v. Senior* (1898), 1 Q.B.D., 283, defending counsel argued that these words were not satisfied by proof of mere omission to provide medical aid. Lord Russell of Killowen, C.J., however, observed: "It would be an odd result if we were obliged to come to the conclusion that in dealing with such a subject as the protection of children the legislature had meant to take what may be described as a retrograde step; for the course of legislation and the provisions of the Act of 1894 show an increasing anxiety on the part of the legislature to provide for the protection of infants." The conviction was thereupon affirmed, but in 1908 Parliament thought it desirable to strengthen the law on the matter, and passed the Children's Act, 1908, Section 12 providing that "a parent or other person legally liable to maintain a child . . . shall be deemed to have neglected him in a manner likely to cause injury to his health if he fails to provide adequate food, clothing, medical aid, or lodging for the child." In *R. v. Senior*, too, the question was raised as to whether lack of means with which to obtain medical aid would be a good defence to a charge of manslaughter, but this is also provided for in the same section, which requires the parent to procure medical aid under the Poor Law Acts.

#### A MODEL MATERNITY AND CHILD WELFARE CENTRE.

ABOUT six years ago the Carnegie United Kingdom Trust, which exists to administer the philanthropic bequests of the late Mr. Andrew Carnegie, decided to select six thickly populated areas in the United Kingdom—three in England, and the others in Scotland, Wales, and Ireland—as places in which to build and equip model maternity and child welfare centres on the condition that the local authority in each place would provide the site and the cost of maintenance. Of these projected centres one at Birmingham and another at Motherwell in Scotland have been at work for some months, and on December 15th the centres at Liverpool and at Shoreditch in London were opened, the latter by Princess Mary, Viscountess Lascelles. Lord Elgin, in handing over the Shoreditch centre to the borough council on behalf of the Carnegie Trust, stated that the trustees were induced to select Shoreditch for the London centre not only because of its crowded population,

but because of the enthusiasm for this work which the borough had already shown. The first plans submitted to the Trust by the borough council would have entailed an expenditure of £100,000, and were thought to be too ambitious, and the borough council eventually submitted new plans to cost £25,000. This sum the Trust had paid for the building and equipment of the centre; the borough council had purchased the site (in Kingsland Road) for £6,000, and had agreed to maintain the institution in full efficiency. The building is quite a noble one in its architecture and decoration, in striking contrast to the poor, adapted buildings which so often serve this purpose. In the main hall, which is to be used principally for lectures and classes, dinners are to be provided daily for a number of nursing and expectant mothers. As an annex to this hall there is a pleasant nursery where the children of these mothers will be minded. Along the side of the hall several small rooms open out, and these are to be used for ante-natal and infant welfare consultations, while a dental clinic for mothers and for children under 5 years of age is to be opened shortly. On an upper floor there is a hospital ward for six infants suffering from disorders of digestion, and two small wards for mothers and infants to be used in special cases where the establishment of breast-feeding requires supervision. In the kitchen and laundry the work is done by electricity, and every contrivance there and elsewhere is of the most modern and approved pattern, including the ventilating arrangements and the "Eco" dry cabinets. At the opening ceremony a brief account was given by the Mayor of Shoreditch (Mr. A. T. Parry) of the progress of this movement in the borough, which formerly had an unenviable notoriety for its high infant death rate. The first health visitor was appointed in 1909, a second in 1912, and in the following year the Shoreditch "school for mothers"—a voluntary institution—was opened. At the present time there are six maternity centres in the borough, with five medical men and seven health visitors. A centre in Kingsland Road, a few paces away from the new building, was opened in 1915, but the premises soon proved inadequate, and the Carnegie Trust has now made it possible to erect in its place an institute of great dignity as well as utility, and one which should be visited by those interested in maternity and child welfare work.

#### INFLUENZA AND PNEUMONIA.

It appears from the weekly returns of the Registrar-General that the notifications of pneumonia and the number of deaths ascribed to influenza have recently been appreciably greater than in the corresponding period for 1922. The increase in the number of deaths from influenza is relatively heavy both in London and in the 105 great towns. In some of the large cities of Lancashire there is a small but definite increase in the number of deaths from influenza and a large increase of notified pneumonia. The age distribution of deaths is unlike that of the great pandemic of 1918-19, and resembles more recent experience and that obtained before 1918—that is, the deaths at ages over 45 form a large majority of the total. There is no sign of the sharp change of type, leading to excessive mortality in young adult ages, observed in the great pandemic. The number of cases of pneumonia notified has shown a tendency to increase for some weeks; in the first week of December there was a large increase in the north-western area; Yorkshire, which is usually affected early by respiratory epidemics, has now reported many cases. The notification rate this year, however, does not greatly differ from that of the corresponding weeks of 1922. It is unsafe to prophesy when influenza is in question, but there are at present no indications of anything more than a minor recrudescence of the inter-pandemic

type. We hear of a considerable number of gastro-intestinal attacks occurring in London or among people who have recently visited London. The attacks are characterized by vomiting and diarrhoea, accompanied sometimes by great depression, which may persist for several days, or even as long as a week or ten days. The idea that there is a gastric form of influenza has been discredited, but Peacock in his classical description had little doubt about it. "Cases of this kind," he wrote, "may fairly be regarded as constituting a special form of the disease." The attacks he had seen, however, must have been of a more serious kind than have been observed recently, for he says that they were often complicated by jaundice, and by pains in the head, back, loins, and extremities, which might be severe. He went on to say that the headache was generally intermittent, and was accompanied by restlessness, agitation, loss of sleep, and some delirium. He mentions also epistaxis and profuse sweating.

#### A DEEP X-RAY THERAPY DEPARTMENT.

Our advertisement pages this week contain an announcement inviting applications for the post of whole-time radiologist to carry on work in the newly established deep x-ray therapy department at St. Bartholomew's Hospital. We understand that the deep x-ray therapy apparatus is being set up for the sole purpose of the treatment and study of malignant diseases, from which it is evident that the medical man chosen to take charge of it should be well acquainted with physics and have some experience of research. The appointment will be for a period of from two to five years, and it is proposed that the successful applicant shall spend the first three months of his term of office in visiting similar departments at home and abroad. As will be seen from the advertisement, the amount of salary depends on the qualifications and experience of the person appointed. We learn that a corresponding appointment has lately been filled at Guy's Hospital, which has been fortunate enough to secure a radiologist both able and willing to provide his own apparatus, and to undertake all the necessary work himself. Applications for the post at St. Bartholomew's Hospital must reach the clerk to the governors by February 29th, 1924.

#### TUBERCULIN AND THE TUBERCULIN DISPENSARY.

In our issue of December 8th (p. 1107) we published a leading article in relation to a recent essay by Dr. Camac Wilkinson on the tuberculin dispensary for the poor. The essay itself was a reply to a report made on his work by the Tuberculin Committee of the Medical Research Council. This report was stated in the preface of his book to be of a confidential nature, and at the time of writing we were unfortunate enough to overlook the fact that it had recently been handed to the *Lancet* for open publication, and was published in our contemporary's issue of November 3rd, 1923 (p. 924). For this oversight we tender an apology to our readers. In self-justification, however, we must say that even if we had had the benefit of reading this report it would have made no difference to the criticisms which we offered on Dr. Camac Wilkinson's work. We felt strongly that the evidence put forward by him was insufficient to support the conclusions which he reached, and after reading the report to the Medical Research Council we feel even more strongly that this evidence is defective. The case records do not appear to have been kept in such a manner as to allow of an accurate analysis being made, and until this is possible we must remain sceptical of any premature conclusions which may be drawn from them.

UREA-VIOLET MAY TREATMENT OF RICHETS.  
 L. E. HOLT, L. WILKINS, and F. H. BOONEN,  
*Bureau of Children, October, 1923, p. 359* report  
 of a series of experiments undertaken with a view  
 of determining the effect of urea-violet in  
 the treatment of rickets. The work of previous  
 investigators has established the fact that the  
 disease is due to a deficiency of calcium in the  
 blood. The present work was designed to determine  
 whether or not the administration of urea-violet  
 would increase the calcium content of the blood  
 and thus cure the disease. The results of the  
 experiments are as follows:

Tuberculosis of the Urinary Organs.

[illegible][illegible]

## FOOD POLLUTION.

In their passage from the source of production to the consumer many articles of food are exposed to preventable contamination. It is difficult to understand why such contamination is allowed to continue, for it is not confined to dark, insanitary kitchens, bakehouses, and the like, only to be discovered by the vigilant health officer, but it is daily and hourly brought to the notice of the general public in shops, market stalls, street stalls, costermongers' wagons, and on railway stations. The consumer cannot claim ignorance of the conditions under which much of his food is supplied to him, and it really rests with him to demand an alteration in those conditions. The jeweller, the draper, the bookseller, the chemist, and even the ironmonger take the most scrupulous care against the soiling of his merchandise, all of which can be readily cleansed; but the baker, the butcher, the fruiterer, the fishmonger, and the grocer expose their wares to the dust and dirt of the street. On more than one occasion Dr. Charles E. Goddard, M.O.H. Harrow, has drawn attention to the many opportunities there are for a loaf of bread to become polluted between the bakehouse and the table. In a paper<sup>1</sup> to the Congress of the Royal Institute of Public Health in May last he returned once more to this subject, and pointed out that the obvious remedy was to place each loaf in a separate wrapper as soon as it is removed from the oven. A machine has been devised for this purpose which is coming more and more into use in large bakeries in this country, and especially in the northern counties. The only objection raised to it on the part of the bakers is that it adds to the cost of production, and that the consumer is not willing to pay his share of that cost. To this Dr. Goddard replies that if waxed paper is used evaporation is lessened, and there need be no stale loaves, while incidentally no night baking will be necessary because the condition of a loaf a day old is indistinguishable from new bread, and deliveries need not be so frequent. If Dr. Goddard's contention is correct—and there ought to be no great difficulty in proving or disproving it—there is no valid reason why the delivery of bread in wrappers should not become the universal custom.

## THE R.A.M.C. BADGE.

The rank and file of the Royal Army Medical Corps have been wearing on their uniform, since the date of its formation in 1898, two badges. One was the familiar small red cross within a circle on the upper arm of the sleeve of the tunic and great-coat of the corps, and the other the badge with the rod of Aesculapius within a laurel wreath over the motto "In Arduis Fidelis," which was registered as the corps badge on its reorganization in 1898. The old badge of the Geneva Cross previous to that time was the distinctive badge of the Army Hospital Corps and Medical Staff Corps; it continued to be part of the uniform after the R.A.M.C. was formed. The Army Council has now decided to abolish the old badge as a distinctive mark on the uniform of the R.A.M.C., and to retain only the badge authorized as the R.A.M.C. badge in 1898. In time of war, however, the Red Cross brassard will be worn by all ranks, attached to the left sleeve, in accordance with the Geneva Convention of 1906. This brassard must be stamped and issued by competent military authority on the outbreak of war only, and will be worn by members of authorized voluntary aid organizations as well as by the officers and other ranks of the R.A.M.C.

The *London Gazette* of December 18th announces that the King has appointed Sir Robert William Philip, M.D., to be one of the Honorary Physicians to His Majesty in Scotland, in succession to Dr. David W. Finlay, deceased.

<sup>1</sup> *Journal of State Medicine*, December, 1923, p. 585.

## THE PRICE AND UNIT VALUE OF INSULIN.

## ANNOUNCEMENT BY THE MEDICAL RESEARCH COUNCIL.

The Medical Research Council announces that the retail price of insulin in this country is to be reduced by the manufacturers, after December 31st, to 12s. 6d. per bottle of 100 units. The price since July has been 17s. 6d., and before that the price was 25s. A reduction of 50 per cent. has accordingly been made since insulin first came on the market nine months ago. This is to be attributed to the increased efficiency of manufacture and to the larger scale of production following the growing demand.

It is of interest to compare the progressive reduction in price here with the corresponding fall in America. It must be remembered, however, that the American manufacture began some months before the British, that the demand and consequently the scale of production is larger there, and that advantages in respect of large slaughtering centres and lower cost of alcohol exist in America which are not enjoyed by the British firms. In April last the retail price in America, formerly higher, was 2d. per unit, or 2½d. in an alternative dilution: the price here was 3d. per unit. The American price was then reduced to just over 1½d. per unit, and in July the British price fell to approximately 2d. per unit. A more recent reduction in America brought the price there to just under 1½d. per unit, and the new British price is 1½d. per unit.

Some further reduction in price may be found possible by the manufacturers in the course of time as the scale and therefore the economy of production increases. It is not, however, to be expected—apart from the possibility of new sources or methods being discovered—that the price can ever be brought to a low level. The manufacture of insulin on a commercial sale involves the collection of large quantities of pancreas in very fresh condition, the use of large amounts of alcohol, elaborate and delicate chemical operations requiring skilled supervision, and careful physiological testing at different stages. The cost of such items must remain high in a process which gives a small yield of the final product.

The manufacturers of the American insulin announce an increase of 40 per cent. in the value of the unit of activity, and quite properly give a scale of dosage for their product revised in accordance with this increase. This announcement makes it advisable to explain the relation of the American unit to that adopted in this country. The Medical Research Council were made aware in August of this year of the discovery of a divergence between the unit adopted in Canada and that adopted by the manufacturers in the United States. They gathered that a proposal was under discussion to remove this difference by raising the value of the American unit by about 40 per cent. At that time American insulin had for a period not been in use in this country, and investigation showed that, during the interval, the value assigned to the British unit had been rising gradually, until it had become so nearly equivalent to the Toronto unit that a very small further adjustment was needed in order to make it correspond to the higher value which, in due course, came into force for the American continent. The value of the unit employed for British insulin is, therefore, already the same as that of the newer and stronger American issue; the only difference between the two countries, in this direction, has been that the value of the American unit has been suddenly raised, so that revision of dosage is needed, whereas that of the British unit has been allowed to rise by small stages, so that dosage has, in practice, adjusted itself. Henceforward all the insulin available in this country will, as originally planned, be standardized to the same unit.

The reduction of price mentioned above has been made in spite of this enhancement in the strength of the unit, so that the total effective reduction in cost to the patient is much larger than appears from the figures of price revision.

453. **Stabilization of Paralyzed Feet.** I. W. RYMERSON (*Journ. of Bone and Joint Surg.*, 1953, 35, 453) discusses the methods for stabilizing feet, a subject which has attracted a great deal of orthopaedic surgeons during recent transplantation in infantile paralysis. He has excellent results, but in feet with much late of a varus or valgus deformity. Midline coupled with subastragloid arthrodesis enabled to obtain a foot stabilized in the lateral ankle-joint proper. Such power as remains certainly that that disabling lateral deformity. Many methods of performing such an arthrodesis during recent years, and the name Hoke in America and Dunn in England are the operation. The author prefers a double the inner and outer sides of the foot. H astragaloecomy is the best operation for calcus and that simple equinus can be best treated I amodises after the method of Gallei. The a fact well known to orthopaedic surgeons that desiring operations, while they may be done a more likely to be successful when performed over 12 years of age.

[illegible]

Dr. BÄUDER (*Univ. et Alem. Soc. Chir. de Paris*, 1892, p. 1162) points out that in the usual operation several large veins which constantly supply the external carotid artery are frequently and landmarks may be observed in the field. It is desirable to approach from in front of the jugular vein, it is better method used by the majority of surgeons, which is recommended by BÄUDER, and the approach to the sternomastoid. The jugular vein runs forwards with its tributaries, and the two branches are now well exposed, with the approach to the sternomastoid.

consolidated and nonpainful. The right side, with paresis, gradually improved. Three weeks after the onset of the right arm and leg, and involvement of the right facial, hypoglossal, and motor nerves. The tendon reflexes were exaggerated and there was transient fever. The spinal nuclei were apparently good, there was no optic neuritis nor dystalgias, and transient relief. Six weeks after the onset of the left side became parietic. The patient died six weeks after the onset of the first symptoms. *Post mortem*, the meninges and cerebral cortex were found to be normal; there was no lesion of the basal ganglia, but the pons was markedly enlarged, especially on the left side. An incision through the centre showed a normal appearing white matter and the whole of the central part of the bulb and upwards to the peduncles. This explained the compression of the pyramidal tracts, especially of the left tract above the decussation, and also of the oculomotor nerves. Histologically the tumour proved to be a gliosarcoma.

K. Csépai, B. Fornert, and K. Tóth (Wien, Arch. f. inn. Med., July, 1923) record their observations on the action of adrenaline on the system (adrenalin sensitivity) in a number of diseases. As indications for the adrenalinic sensibility, and hyperglycaemia, or the changes in the pulse and blood pressure, have been chiefly employed, but the authors consider the most convenient and the simplest indication is the increase of blood pressure. After injection (preferably intravenous) of 0.01 mg. of adrenaline the blood pressure rises normally to over 10 cm. but not over 30 cm. (Reeklinghansen's apparatus), and within two minutes it falls to its original level, the maximum duration of the rise of blood pressure being usually between thirty and forty seconds. In numerous cases of Graves's disease the adrenalin

552. **Cancer of the Tongue.**

P. E. THURSDALE (*Annals of Surgery*, October, 1923, p. 461), reviewing the literature, finds that cancer of the tongue is on the increase and stands fifth in order of frequency as compared with other regions of the body. Butlin showed that cancer of the tongue may first appear as a hard plaque, or start in a patch of leucoplakia, in a simple ulcer, or as a warty growth. The initial stage lies between the middle period of the disease, and it is during this period that the growth passes from the operable to the inoperable and hopeless stage. The cardinal symptoms at this period are ulceration, hæmorrhage, pain, salivation, anæmia, and loss of weight. In the initial stages the disease must be a local process, but lymphatic infection occurs in many cases before the diagnosis has been established. Prognosis is not hopeful in patients under 40 years of age, except in the initial stages. In the absence of operative treatment the average duration of life is two years. The operative mortality is now not more than 5 per cent., and the proportion of cures persisting after three years is at least 30 per cent. The treatment is surgical in the operable stages; x rays and radium are found to be disappointing. The author advocates the use of the cætery for the purpose of disseminating the loss of blood is slight by this method, and the time employed in tying vessels in the course of the knife operation is saved. A few days are devoted to oral hygiene before the operation. Either is

352. F. E. TRUESDALE (*Annals of Surgery*, October, 1923, p. 461), reviewing the literature, finds that cancer of the tongue is on the increase and stands fifth in order of frequency as compared with other regions of the body. Butlin showed that cancer of the tongue may first appear as a hard plaque, or start in a patch of leucoplakia, in a simple ulcer, or as a warty growth. The initial stage then passes into the middle period of the disease, and it is during this period that the growth passes from the operable to the inoperable and hopeless stage. The cardinal symptoms at this period are ulceration, hæmorrhage, pain, salivation, anæmia, and loss of weight. In the initial stages the disease must be a local one, but in the later stages it occurs in many cases before weight and hæmorrhage are noticeable.

352. F. E. THURSDALE (*Annals of Surgery*, October, 1923, p. 461), reviewing the literature, finds that cancer of the tongue is on the increase and stands fifth in order of frequency as compared with other regions of the body. Butlin showed that cancer of the tongue may first appear as a hard plaque, or start in a patch of leucoplakia, in a simple ulcer, or as a warty growth. The initial stage then passes into the middle period of the disease, and it is during this period that the growth passes from the operable to the inoperable and hopeless stage. The cardinal symptoms at this period are ulceration, hæmorrhage, pain, salivation, anæmia, and loss of weight. In the initial stages the disease must be a local process, but lymphatic infection occurs in many cases before the diagnosis has been established. Prognosis is not hopeful in patients under 40 years of age, except in the initial stages. In the absence of operative treatment the average duration of life is two years. The operative mortality is now no more than 5 per cent, and the proportion of cures persisting after three years is at least 30 per cent. The treatment is surgical in the operable stages; x rays and radium are found to be disappointing. The author advocates the use of the canterbury for the purpose of dissection; the loss of blood is slight by this method, and the time employed in tying vessels in the course of the knife operation is saved. A few days are devoted to oral hygiene before the operation. Either is

## England and Wales.

### MEMORIAL TO PROFESSOR DELÉPINE.

A MEMORIAL to the late Professor Sheridan Delépine was unveiled by Sir George Newman, the chief medical officer to the Ministry of Health, on Wednesday, December 12th, at the Public Health Laboratory, Manchester.

The memorial, which takes the form of a bronze bust and is the work of Millard, has been placed on the main staircase. The ashes of Delépine have all along lain in the building he founded, and the present memorial has been presented by his former pupils and colleagues. The bust bears the following inscription:

Auguste Sheridan Delépine. Born January 1, 1855. Died November 13, 1921. Founder and first director of the Public Health Laboratory. Professor of Pathology 1891-1924. Professor of Public Health and Bacteriology 1924-25.

The ceremony was attended by Mrs. Delépine and her daughter, and a large and distinguished gathering of members of the medical profession.

Sir George Newman, in unveiling the bust, said:

It is fitting and appropriate that a memorial should be placed here to Auguste Sheridan Delépine to keep alive for generations to come the memory of his great public service to this University, this City of Manchester, and to the public health of the nation. Delépine was born in 1855, the son of a French father and a Swiss mother. He was educated in Paris and graduated in the University of Geneva as B.Sc. in 1872. His medical education was obtained in the University of Edinburgh, where he graduated with first-class honours in 1882. In 1891 he was appointed Proctor Professor of Pathology and Morbid Anatomy in the University of Manchester. The arrangements for the new pathological department at Manchester associated with the bacteriological laboratory were carried out under Delépine's instructions, and when later the connexion between the University Medical School and the Royal Infirmary became the close one it now is, he became the official pathologist. In 1901 he relinquished the post of professor of pathology and was appointed director of the new public health laboratories, thus becoming a pioneer in assisting a University with the training and work of the medical officer of health. In Dr. Niven, who came to Manchester in 1894, Delépine found a congenial and worthy colleague, and these two laboured together in a partnership of scientific and public work which has been of inestimable value to Manchester and the whole country.

As examples of Delépine's wider work may be quoted his investigations in connexion with the remarkable epidemic of poisoning from arsenic in beer in 1900; his studies in the bacteriology of milk; and his investigations for the means of disinfection of wool for anthrax.

Delépine was an indefatigable workman and laboriously conscientious, reluctant to publish his results until he was satisfied that his conclusions were valid and invulnerable. Taking him altogether, he seems to have compounded in himself some of the fundamental requirements of the new model of public health officer, to the consideration of which we may confidently invite the students of to-day and to-morrow. We cannot place Delépine alongside his incomparable fellow countryman, Louis Pasteur, yet it is not extravagant to say that he belonged to the same race and had in no small degree two of Pasteur's chief characteristics—love of truth and love of humanity.

It is a great and splendid thing for a university and city to have such a man as Delépine, and we do well to-day to enshrine his memory that generations of students may follow in his footsteps and climb up after him, and that every workman may work the better for his labours.

On the conclusion of the unveiling ceremony, the Vice-Chancellor, Sir Henry Miers, accepted the bust on behalf of the University as "a cherished memorial to one of our greatest teachers and investigators."

### BRISTOL MEDICAL SCHOOL.

At the recent annual dinner of the Bristol University Medical School, held at the Grand Hotel under the presidency of Professor Walter Swayne, the guest of the evening was Sir Ewen J. Maclean, professor of gynaecology and obstetrics in the Welsh National School of Medicine. Dr. J. A. Nixon, dean of the Bristol Medical School, in proposing the health of the principal guest, congratulated the Cardiff Medical School on having now completed its organization, and referred to their guest's previous connexion with the Bristol Children's Hospital. Sir Ewen Maclean, in reply, read a message of greeting from the

Cardiff medical students, and mentioned that when he was practising in former days at Bristol he came into touch with Dr. W. G. Grace, who often visited patients in the same street. He then proposed the toast of the Bristol Medical School, and the President's health was proposed by Mr. R. G. P. Landown, consulting surgeon to the Bristol General Hospital.

### POST-GRADUATE COURSES IN LONDON.

The following arrangements have been made by the Fellowship of Medicine and Post-Graduate Medical Association:

*Infants' Hospital*, Vincent Square, S.W.—A further course in children's diseases, from January 7th to 19th, specially adapted to the needs of medical officers of welfare centres, and including clinical lectures, demonstrations, and visits to places of interest in connexion with infant welfare work.

*St. Peter's Hospital*, Covent Garden—An intensive course in urology, from January 7th to February 2nd inclusive, consisting of clinical work and lecture demonstrations.

*West End Hospital for Nervous Diseases*—A course of lectures on four afternoons in each week on the diagnosis and treatment of common diseases of the nervous system, from January 7th to February 11th, in the out-patient department, 75, Welbeck Street; there will also be clinical demonstrations.

*North-Eastern Fever Hospital*, Tottenham—A series of eight demonstrations of the diagnosis and treatment of the acute infectious fevers, by Dr. F. Thompson, on Wednesday and Saturday mornings at 11 o'clock, from January 5th to 26th.

Copies of the syllabus of each of the above courses can be obtained from the Secretary to the Fellowship of Medicine, 1, Wimpole Street, W.1.

## Scotland.

### BRITISH MEDICAL ASSOCIATION'S RECEPTION FOR THE NEWLY QUALIFIED AT EDINBURGH.

THE Edinburgh and Leith Division of the British Medical Association on December 11th held a reception in the Hall of the University Union for those who were to graduate on December 14th. About 120 of the graduands were present, and were received by Dr. John Stevens, Chairman of the Division, and some 50 members accompanied by ladies. A copy of the *Handbook for Recently Qualified Medical Practitioners*, which has been prepared by the Association, was handed to each of the graduands. After tea, the Chairman, on behalf of the Association, made an expression of welcome into the ranks of the profession, and an address was delivered by Professor G. Lovell Gulland, C.M.G., the newly elected President of the Royal College of Physicians of Edinburgh, who referred to the special necessity under the changing conditions of the present time for union and co-operation between medical men. The organization which was capable of voicing the collective needs and wishes of the medical profession, and of obtaining attention to these, was the British Medical Association, and he advised them all to lose no time in joining it. With regard to the choice of a career, one of the first lines of life to which attention naturally turned was the public services, and among these he considered that the R.A.M.C. at the present time occupied a high place. He hoped that some of them would decide to adopt this service as a career. In all public services it was possible to lead an easy life, but promotion in the Services, as in all callings, came to the man who worked hardest. It must not be forgotten that the greatest of all public services was general practice, and this should be regarded as the highest and most interesting department of the medical profession. The general practitioner held a position of great honour in the community, for he was not only consulted in matters of illness, but he became the general guide and confidant of his patients in all affairs of life. The attitude of practitioners towards one another had changed greatly in recent times. In the past, social factions in small towns had often centered round the different doctors, who might not be on speaking terms with one another. Now, that had altogether changed, and doctors co-operated with one another in their cases, in doing holiday duty, and the like. It was a good rule never to listen to any remarks that a

3 0721

2071

respect of the period from July, 1921, to June, 1926. The selection of additional benefits to be provided by a society rested with the members, and he did not think it desirable to introduce legislation to compel allocation for a particular object. Mr. Gerald Hurst mentioned that the Manchester Royal Infirmary spent about £70,000 a year maintaining nearly 5,000 persons insured under the Act without drawing any substantial contributions from approved societies.

**Eyesight and Workman's Compensation.**—Mr. D. G. Somerville asked, on July 4th, whether in view of the request for the inclusion of eyesight failure in the Workmen's Compensation Act the Labour Department possessed any reliable record showing how the several senses were affected by particular industries; and whether steps were taken to differentiate at any stage between failure due to advancing years and to conditions of work. Mr. G. Locker-Lampson replied that the Home Office possessed a great deal of information as to diseases and affections caused by particular industries and processes, but so far as regarded failure of eyesight it would not be possible to differentiate between the effect of the conditions of work, advancing years, and other possible causes. Asked as to railwaymen, Mr. Locker-Lampson said that certain affections of the eyes were already included under the Act of 1906 and the number was being added to.

**School Dental Service.**—Mr. Wood, the Minister of Education, on July 5th said that the Board of Education fully recognized the value of the school dental service, and proposals for its extension would receive sympathetic consideration. The number of authorities who had approved schemes for dental treatments had nearly doubled since 1914, but 25 per cent. of the county educational authorities had not provided school dental services. The percentage of county boroughs not providing services was 15, of boroughs 26, and of urban districts 23.

**India and Opium.**—During the debate, on July 5th, on the India Office Vote, Mr. Ponsonby said that the attitude of the Indian Government to the opium question was putting an obstacle in the way of reform. The United States Government had formulated a project for restricting the production of opium and the matter had come before a committee under the auspices of the League of Nations last month, but the representative of the Indian Government had entered a reservation that entirely blocked the way. The contention was that the use of raw opium in India according to established practice and its production for such use was not illegitimate under the Opium Convention. He appealed to Lord Winterton, Under Secretary for India, to state the precise reason for India's refusing to join with the other powers, and declared that the world used 125 tons of opium annually for medicinal and scientific purposes while 1,350 tons were "scattered broadcast." In reply Lord Winterton said that India had carried out to the letter the Hague Convention on opium, and had reduced the poppy cultivation from 613,000 acres in 1905-6 to 117,000 acres in 1921-22. He denied that India had taken up an outrageous attitude at the recent convention in Geneva, and said that when the resolution before the convention was eventually passed the American delegates accepted the reservation made by the Indian representatives.

**The Adjustment of Taxation.**—On the Third Reading of the Finance Bill, on July 4th, Sir Sydney Russell-Weils referred to numerous criticisms made against the Government for having reduced the duty on beer and not that on sugar, and also for maintaining the duty on tea at the present rate. Tea, he said, was undoubtedly an article of inestimable benefit to men and women, and the argument was used that it should never be taxed, because it was a food. On the other hand, beer was said not to be a food. The real facts were that tea was a pure drug without any food value, but beer, while it contained alcohol, contained food, and the amount or nutriment in a glass of beer was very considerable. It was not in the alcohol, but in other substances present in beer. Sugar was not a necessary; for many centuries no sugar was eaten in this country at all. Sugar was undoubtedly nourishing, but the number of calories in a gram of sugar was not as great as the number in a gram of starch. Money spent on buying sugar, even at the old price of 2½d. a lb., did not produce so much nutriment as would be obtained if the money were spent on wheat. Sugar was a luxury which all classes of the community consumed. After speaking generally in support of the Budget, Sir Sydney referred to the burdens of the income tax payers. The struggling professional man constituted a large proportion of the community, and to say that he was not as deserving of some assistance as the unemployed was not true. Those who had contributed the bulk of the taxation and borne the bulk of the burden should have relief if it were given in fair proportion.

**Midwifery Fees.**—In answer to Dr. Fremantle, on July 4th, Mr. Chamberlain said that the Order of 1847 as to fees had not been revised, but in a number of cases special arrangements between the guardians and their medical officers as regards midwifery fees had already been approved. He would consider the question of a revision of this part of the Order.

**Royal Army Medical Corps.**—Mr. Becker asked, on July 10th, if all officers in the Royal Army Medical Corps eligible for selection to the higher ranks were personally interviewed by the Selection Board, and whether assurance would be given that none would be passed over who was not so interviewed. Colonel Guinness replied that a system of inviting officers to attend and make out a case for their own promotion would not be at all satisfactory, even if all the officers concerned were always available for such attendance, which they were not. It rarely happened, however, that an officer was not known personally to the majority of the selectors.

### Answers in Brief.

Mr. Chamberlain has stated that draft regulations as to the labelling of skimmed dried milks had been prepared and were being circulated for preliminary discussion, and that it was expressly provided in the Milk (Special Designations) Order, 1923, that milk sold as "pasteurized" milk should not be heated more than once.

Mr. Chamberlain said that the Government could not undertake to introduce legislation as to "patent" medicine during the present session.

The Under Secretary for Health, Scotland (Captain Elliot), has stated that the number of deaths in Scotland from tuberculosis was 5,737 in 1921 and 5,818 in 1922.

The Minister of Education is unable at present to reconsider the existing arrangements as to the absence of children from elementary schools to receive sanatorium, hospital, or other medical treatment when ordered by the school medical officer. Such absences do not count as attendances under the code.

The Ministry of Pensions is issuing new regulations to have x-ray examinations made in doubtful cases to try to avoid such errors as in a case to which Colonel Ward called attention where a man had applied for a pension on the ground of neurasthenia and was found subsequently to have a jagged piece of shrapnel near the heart.

Major Tryon said that at the cost of the Pensions Ministry approximately 76,500 officers and men were receiving treatment, of whom about 41,600 were prevented by the treatment from following their occupations. Of these 18 were in military hospitals and 3,650 in general hospitals. These figures did not include men receiving treatment, without allowances, from their panel practitioners, of whom the Ministry had no record.

The average cost per day of pensions patients at hospitals under the direct control of the Ministry of Pensions was 8s. 2½d. each.

## England and Wales.

### UNIVERSITY COLLEGE, LONDON.

A RECEPTION given at University College on July 7th was attended by head masters and head mistresses of schools, by many diplomats and official guests, and by a large number of old students. The object was to afford the visitors, who numbered some 3,000 persons, an opportunity of seeing some of the recent extensions of the College buildings, and in particular the new building for anatomy and the extension of the physiology and pharmacology buildings, made possible by the Rocketteller benefaction. A statement presented on the occasion showed the gradual progress which has provided the great series of buildings now at the disposal of the College, of which in future the British Medical Association will be a near neighbour. The main block, erected in 1827 from the designs of Mr. William Wilkins, now contains the libraries and the Flaxman Gallery. The Birkbeck buildings, erected in 1847, now houses part of the department of applied mathematics and mechanics, while the Brundrett block, erected in 1894, includes the general laboratory of physics. The south wing, erected between 1869 and 1874, provides most of the classrooms of the Faculty of Arts. The north wing, built between 1871 and 1881, includes the Slade School of Fine Art and the department of botany and zoology. The engineering wing, begun in 1894, has been completed this year by extensions recently opened. The chemistry laboratories, lying on the north side of the main College building, were completed in 1913, the Bartlett School of Architecture in 1913, and the department of eugenics in 1914. To the south of the main College buildings lies the medical sciences block, of which the Physiology Institute was erected in 1909, the Pharmacology Institute in 1912, and the anatomy building in 1923. To the east of the main block lies the Great Hall, formerly All Saints' Church, Gordon Street, which will be converted into a war memorial hall. In all departments the visitors were shown objects of interest. In the Flaxman Gallery was the panel by the Slade Professor (Henry Tonks) representing four of the founders, Jeremy Bentham, Thomas Campbell, Henry Brougham, and Henry Crabb Robinson. In the general library the librarian, Mr. L. Newcombe, had on exhibition a number of manuscripts, a collection of English chronicles, and a number of early printed books, as well as bindings from the fourteenth century onwards. Demonstrations were given in the department of physiology and in the new anatomy building; in the department of electrical engineering wireless telephony transmitters and receivers and a

number of other interesting apparatus and experiments open for inspection. The last demonstration was by Miss Ida Ward on the use of phonetics in curing speech defects. University College Hospital and its medical school were also open to inspection.

**QUEEN'S COLLEGE, BIRMINGHAM.** After being closed for some years, Queen's College, founded by Birmingham medical men in 1828, will resume its activities in October. As the old buildings in the heart of the city proved unsuitable the Council has purchased and converted into a residential college Bishop's Croft, the residence of the Bishops of Birmingham. Here a medical student can obtain all the advantages of college life and the full course of the medical school and the university and hospitals for £150 per annum inclusive. In view of the increased costs at Oxford and Cambridge and elsewhere, many will be glad to know that the endowments of this nearly century-old foundation are once more available for the furtherance of medical education. The College has some exhibitions, of which the principal will gladly send particulars.

#### LIVERPOOL COURSE FOR PHARMACEUTISTS.

The hospitals comprising the Liverpool Clinical School have arranged to hold lecture demonstrations for practitioners during the University terms. The programme is given by one hospital only. This in each week, except at the third week in the month, a demonstration will be given by the Royal Liverpool Children's Hospital on Monday, at the Royal Northern Hospital on Tuesday, the Stanley Hospital on Thursday, and the Royal Infirmary on Friday. In the third week in each month there will be a demonstration at the Hospital for Women, Shaw Street, on Monday, at the Liverpool Maternity Hospital on Tuesday, St. Paul's Eye Hospital on Wednesday, St. George's Hospital for Skin Diseases on Thursday, and Eye and Ear Infirmary on Friday. The lecture demonstrations, which will begin at 3.30 p.m. on each day, will be largely clinical in character. No fee will be charged. Further information can be obtained from the Secretary of the Clinical School of the University of Liverpool, 61, Rodney Street.

#### THE HISTORY OF THE ROYAL SOUTHERN HOSPITAL, LIVERPOOL.

A jubilee commemoration history of the Royal Southern Hospital, Liverpool, compiled by Dr. Charles J. Macalister, has been issued with an appeal for funds. The hospital was founded in 1858, as the Southern and Toxteth Hospital through the efforts of medical men and a provisional committee of "parties favourable to the formation of the institution"; the first building was opened for the reception of patients in 1842. In 1849 the committee, looking for ways and means, secured the services of Miss Jenny Lind, with such good effect that £1,300 was obtained. Thus, as the report states, "the requirements of taste and fashion came in aid of the calls of humanity." In memory of her kindness a ward in the present hospital bears her name. In 1857, the number of beds at first only 50, had increased to 100, and it is noteworthy that a special children's ward, opened. The name of the hospital was now changed to the Southern Hospital, and as there were now two physicians on the staff, the hospital was recognized by the Royal College of Surgeons and the Society of Apothecaries as an institution where students could be trained for the qualifying examination. Eleven years after the completion of the building, which received additions as funds accumulated, the sanitary conditions of the hospital left much to be desired. In 1861 it had to be closed for three months owing to an outbreak of fever apparently introduced by sailors suffering from dysentery and typhus. In spite of humble attempts at remedying the hygienic conditions, the committee decided, in 1864, that an entirely new building

A list of the medical and surgical staffs and residents in sobriety, described. medical officers of the first years of professional life were associated with their to whom this record of an institution with which their first years of professional life were associated will be particularly attractive.

**CENTRAL MIDWIVES BOARD.** The monthly meeting of the Central Midwives Board for England and Wales was held on June 21st, Sir Francis Champernowne presiding. A letter had been received from the Ministry of Health approving the present rules for a further period of six months from July 1st, 1923. It was decided from him, that (a) the Board has for a long time represented that the words "habitually and for gain" ought to be deleted from Section 1 (2) of the Midwives Act, 1902, and hopes that in the near future legislation will effect what is desired; (b) that the Board thinks that the suggestion of a registered medical practitioner "is impracticable; (c) that whilst appreciating the desirability of ensuring that practising midwives notify their intention to

would be essential if the hospital were to serve its main object, and in 1867 a fresh piece of land was obtained and the foundation stone of the present hospital was laid by the Earl of Derby. In May, 1872, the new building was opened by Prince Arthur, the present Duke of Connaught, and the prefix Royal was added to the name. In September, 1872, it was used for the reception of patients. During the last fifty years notable additions have been made. In 1891 a detached nurses' home secured next for the nursing sisters, who, up to that time, had bed-sitting rooms attached to the ward. In 1910, a new out-patient department was opened and called "the William Adamson Out-patient Department" in recognition of the signal services rendered as a member of the committee and president of the hospital by the late Mr. W. Adamson for close upon fifty years. Of the other activities of the hospital, mention should be made of a ward for tropical diseases by Lord Lister in 1889, while the clinical work was carried on until 1911. With the opening of the new laboratory for tropical diseases adjoining the university, the clinical work was transferred to the Royal Infirmary. The present appeal in commemoration of the jubilee is for money to complete the electro-therapeutic and massage department, and for the raising of an endowment fund for after-care work. In the surgical experience of the hospital Dr. Macalister has given an epitome of the advances due to antiseptic and aseptic methods. The late Dr. William Alexander, Mr. Frank T. Paul, and Sir Robert Jones were makers of the surgery in the Royal Southern Hospital. On the medical side the name of Dr. John Cameron, the second in order of the physicians attached to the institution, stands out pre-eminently. He was appointed in 1848, and only retired from active work after sixty years' service. Dr. Macalister, in the section dealing with "personal recollections" of past members of the staff, not only has revealed the good work they did but has placed it in a light that shows what manner of men they were. Dr. William Carter, who was appointed in 1870 as physician and retired in 1907, did much to promote the reputation of the hospital, and so highly valued were his services that a new rule was framed to retain them. As professor of materia medica and therapeutics in the university, Dr. Carter was keenly interested in the action of drugs. Experiments on himself are mentioned by Dr. Macalister in an entertaining way. Changes in type of patients are discussed in the concluding section of this history, and the great improvement socially, and especially in sobriety, described.

A list of the medical and surgical staffs and residents in sobriety, described. medical officers of the first years of professional life were associated with their to whom this record of an institution with which their first years of professional life were associated will be particularly attractive.

C. THÉLIN (*Gynéc. et Obstét.*, 1923, viii, 3, p. 313) describes the experience of the Lausanne Maternité from 1907 to 1922 with regard to pubiotomy: the operation was done subcutaneously with a Gigli saw, and subsequently it was the rule to await spontaneous delivery. The cases numbered 26 in all—21 of vertex presentation with pelvic contraction, the true conjugate being not less than 8 cm.; 4 of face or brow presentation in slightly flattened pelvis; and one of presentation of an abnormally large head in a pelvis of normal dimensions. The operation was not done until (1) a test of labour lasting from eleven to forty-eight hours, in the mean thirty-five hours, had proved that natural delivery was not to be expected; (2) the os was sufficiently dilated to permit of labour being, if necessary, terminated rapidly after pubiotomy. Spontaneous delivery followed in 18 cases. In the 26 cases there were 4 foetal and 2 maternal deaths. The subsequent complications in non-lethal cases were numerous and serious, including 4 cases of vesico-vaginal fistula, 3 of thrombo-phlebitis, and one of parametritis. Twelve patients did not leave the clinic until after the thirtieth day; at that time none had difficulty in walking.

#### 462. Menstruation and Pregnancy in Hodgkin's Disease.

A. A. GEMMELL (*Journ. Obstet. and Gyn. Brit. Empire*, Autumn, 1923, p. 373) notes that the majority (53 per cent.) of cases of Hodgkin's disease in the female occur between the ages of 20 and 40. Menstruation is usually affected, the disease giving rise to oligomenorrhoea in the large majority of cases, and in some even to amenorrhoea. In the case of ten married women, six dated the origin of the disease from a pregnancy. Labour is usually normal, but post-partum haemorrhage may be of more frequent occurrence than usual owing to the general liability of haemorrhage during the disease. It would seem that the disease progresses during pregnancy, and thus early therapeutic abortion is advised. The author suggests that ovarian hypofunction may be associated in some way with Hodgkin's disease, and, that being so, he advises the addition of ovarian extract to the other usual therapeutic measures of arsenic and radiotherapy.

#### 463. Threatened Abortion.

J. A. VAN DOUGEN (*Nederl. Tijdschr. v. Geneesk.*, November 10th, 1923, p. 1927) during the last seven years has treated 190 cases of threatened abortion in the Wilhelmina Hospital at Amsterdam and in private practice, with the following results. In 72 patients, or nearly 38 per cent., the pregnancy ended successfully, with the birth of a full-term child or with a premature but viable child, while in 118 cases abortion took place. Some of the 118 cases had been under treatment for only a short time before abortion took place, while others had had slight or severe haemorrhages for weeks or months, or had been discharged from hospital because the haemorrhage had ceased, but subsequently aborted. The prognosis in threatened abortion depends upon the time when medical aid is summoned, the cause of the threatened abortion, and the subsequent behaviour of the patient after discharge from hospital. Van Dougen's treatment is as follows: A careful vaginal examination is first made to determine the existence of intrauterine pregnancy, the size of the uterus, the permeability of the os, and the possibility of any other source of haemorrhage than the uterine cavity. Uterine contractions are prevented by keeping the patient in bed not only during the haemorrhage but for four or five days after it has completely ceased, and powdered opium is given four times a day in doses of 4 mg. Laxatives by the mouth are avoided, and the bowels are emptied by enemata every two or three days.

## Pathology.

#### 464. Amoebic Bronchitis.

M. PETZETAKIS (*Bull. et Mém. Soc. méd. des Hôp. de Paris*, November 8th, 1923, p. 1451) describes eight cases of a new disease which he has encountered in Alexandria. The condition is one of bronchitis, sometimes complicated with bronchopneumonic patches, which appears to be due to an amoeba closely allied to, if not identical with, the *Amoeba histolytica*. The disease often begins with definite constitutional disturbance and febrile manifestations, but the most striking point is the character of the sputum, which is of a glairy, viscous, and frequently sanguineous nature. Blood is generally, though not always, present, and may either be seen in the form of streaks or intimately mixed with the sputum. Examination of the fresh sputum reveals the presence of actively motile amoebae, of an average diameter of 20 to 35  $\mu$ , differentiated into a granular endoplasm and a refractile ectoplasm, and often containing red blood cells. Clinically

the course of the disease is very favourably influenced by the administration of emetine—particularly by intravenous injection—though it may be some time before the amoebae finally disappear from the sputum. It is to be noted that this amoebic bronchitis has nothing to do with pulmonary abscess formation, which very rarely occurs in connexion with dysentery. There is no evidence of suppuration, either clinically, pathologically, or radiographically. The history does not always include an attack of dysentery, and it is therefore doubtful how the infection of the bronchial tract takes place in these cases. It is possible that the amoebae gain access to the respiratory system by infected dust.

#### 465. Distribution of Diphtheria Bacilli in the Body.

M. CHRISTIANSEN (*Ugeskrift for Læger*, August 16th, 1923, p. 581) has carried out a series of investigations at a fever hospital with a view to ascertaining the frequency with which diphtheria bacilli occur in different parts of the body during and after an attack of diphtheria. In a series of 100 cases about to be discharged from the fever hospital to some other institution, he found 40 in which, even after three negative examinations of the nose and throat, diphtheria bacilli could still be found in other sites. Among 200 cases of diphtheria of the fauces there were 51 in which diphtheria bacilli could also be found in the nose. In 29 of these cases there was a nasal discharge; in the remaining 22 cases there were no nasal symptoms. There were also 23 cases of scarlatinal otitis in which diphtheria bacilli were found in the discharge from the ear; in 17 of these cases diphtheria bacilli could not be found in the nose or throat. Among several thousand cases of diphtheria the author has not once seen the membranous diphtheria of the vulva described in the textbooks, but he considers as comparatively common the milder forms of diphtheria of the vulva. Bacteriological examinations of the urine during the acute stage of diphtheria showed that in only one out of seven cases could diphtheria bacilli be found, and it is probable that the urine plays an insignificant part in the dissemination of the disease. Examinations for diphtheria bacilli in the nose and throat of 274 apparently healthy school children revealed diphtheria bacilli in 9. The upshot of the author's investigations is that in densely populated communities the occurrence of diphtheria bacilli after convalescence and among carriers is so frequent that there is little prospect of stamping out the disease by isolation. If every patient who had suffered from diphtheria were kept in a fever hospital till complete freedom from infection could be guaranteed, the cost of running such a hospital would be enormous.

#### 466. Infectivity of Scarlet Fever.

SINDONI (*La Pediatria*, August 15th, 1923, p. 857) has carried out some experiments on the infectivity of the scales in the peeling of scarlet fever. He made an emulsion of the scales in sterile physiological solution and placed it in an incubator at 37° C. for about twelve hours. In this preparation he found the scarlet fever organism described by Cristina and Caronia. Cultures could be made from this which presented typical characters, and positive serological results followed. Seeing that the tendency of late years has been to look upon the desquamating stage of scarlet fever as less infectious, these experiments, showing that a possibly specific germ may be isolated from the desquamating scales, are of some importance.

#### 467. The Action of Ultra-violet Rays on a Strain of Bacteriophage.

In endeavouring to solve the problem as to the animate or inanimate nature of the bacteriophage C. ZOELLER (*C. R. Soc. de biologie*, October 27th, 1923, p. 860) made an experiment in which he submitted a bacteriophage for Shiga's bacillus of medium virulence to exposure to ultra-violet rays. If the principle were destroyed one might be led to conclude that it was of living nature, whereas if, on the other hand, it remained unaltered one might conclude that the reverse was the case. He therefore made the following experiment. A culture of Shiga bacilli suspended in saline was submitted to the action of the rays for a quarter of an hour; cultures taken at intervals showed that it was sterilized in ten minutes. A dilution of the bacteriophage similarly exposed was found to have become completely inactive. Can one, then, conclude that it was alive and had been killed by the destroying action of the rays? No; the author was careful enough to try the effect of ultra-violet light on a principle of known inanimate nature. He took a paratyphoid B agglutinating serum of a titre of 1 in 2,500 and exposed it for fifteen minutes to the rays. He was surprised to find that the titre after exposure had dropped to 1 in 100. If, then, such a principle as the agglutinin in a serum is destroyed by the rays, it is clear that no conclusion as to the living nature of the bacteriophage can be drawn from finding that it also is destroyed.

be treated by surgical means, but most of whom, with our present knowledge, should have been cured by the physician long before surgical interference became necessary. (Cases 12, 13, 14, 15.)

When Sahli published his book on tuberculous treatment by means of very minute and slowly increasing doses of Béraneck's tuberculin without reactions, I at once made use of it as it seemed to be somewhat safer and more reliable. (I shall call this Béraneck's (T.Bk.) treatment (Appendix B).) As I anticipated, it proved to be so. Although the injections were painful for a few minutes the absence of big reactions alone made up for this slight inconvenience. In the early stages of tuberculosis of the lungs and in tuberculosis of the other organs of the body the results were far superior to Koch's treatment (Case 14). The improvement in these cases was steady and devoid of any sudden disappointments and relapses.

Case 9.—January, 1910. Mrs. G., aged 33 years, weight 45 kg. Right apex, third stage. Tubercle bacilli in sputum. Ill some time. Diagnosis: Tuberculous pneumonia. After six months' treatment with T.Bk. the disease apparently arrested. Sputum contained no tubercle bacilli. Relapsed 1915. Twelve months' treatment with T.Bk. Quite well and strong to-day; weight 63.5 kg.

Case 10.—January, 1914. Mr. G. W., aged 20 years. Haematuria; urine contained pus and tubercle bacilli. Ill a few months. Diagnosis: Tuberculosis of the bladder. T.Bk. treatment. Well till the end. No relapse. Picture of health at present.

Case 11.—February, 1917. M., aged 31 years, weight 68 kg. Right apex, second stage. Larynx slightly affected. Sputum contained tubercle bacilli (Gaffky X) and streptococci. Four months' treatment with T.Bk. Apparently well; sputum free from tubercle bacilli. Went to the islands. Weight 85 kg. This patient took apart from other means, about two dozen raw eggs each day, which may account for big increase in weight.

(Case 12.—1913. D. T., aged 15, suffering from tuberculous lymphatic of right knee. Complete cure after six months' treatment with T.Bk.)

(Case 13.—1913. E. T., aged 19, sister of Case 12, suffering from tuberculosis of right hip-joint. Had been operated on a few months before. When first seen by me there were many suppurating sinuses and a temperature of 38.3° C. During the first two months of T.Bk. treatment the temperature rarely dropped below 37.8° C. Treatment lasted twelve months, with the result that the temperature gradually became normal, the sinuses healed up, and the patient could walk about with the aid of a walking-stick. When last heard of about twelve months ago she was employed as a domestic servant.)

(Case 14.—1917. Miss F., aged 16 years. A remarkable case showing the superiority of T.Bk. over Koch's treatment. Some years ago she had pleurisy and peritonitis (tuberculous). Six months ago she developed tuberculosis of the left ankle and right knee joints, for which she was being treated by a specialist with tuberculin injections with very severe reactions. Another physician, visiting another patient at the same boarding-house in which my patient was living, told her mother that in his opinion her daughter could only live another week or two. When called in I found the patient in a deplorable condition: as thin almost as a skeleton, her left ankle had a large unopened abscess, her right knee the size of a small football fixed at an angle of 90 degrees. After having the abscess opened, and without using any splints, I started at once T.Bk. treatment, with the result that in eight months time the right knee was normal, while the left ankle was still but quite movable after an operation under anaesthesia for breaking down some adhesions. Six months after her return from the country she came to see me quite well.)

(Case 15.—One of my first cases treated with T.Bk. at the anti-tuberculous Dispensary is worthy of notice. I cannot get the history chart of this patient—a boy about 18 years old, who had had two amputations already, the first an amputation at the ankle-joint for tuberculosis of the bones of the foot, and the second at the junction of the lower third and upper two-thirds of the leg for tuberculous bone trouble. When seen by me he had several tuberculous sinuses, and had been advised to have the leg amputated at the knee. About twelve T.Bk. injections healed every sinus up.

Case 16.—1917. Mrs. G., aged 35 years, weight 51 kg. Ill twelve months. Sputum contained tubercle bacilli (Gaffky IV). Right apex affected to sixth rib. Diagnosis: Tuberculous pneumonia. T.Bk. treatment. After six months' treatment the disease apparently arrested. Sputum contained no tubercle bacilli. Two years later came to Sydney from her country residence, caught "a cold." During a severe coughing fit expectorated pieces of "marble" and a fair amount of blood. The sputum examination two days later contained many tubercle bacilli. T.Bk. treatment resulted in the disappearance of the organisms, and patient left for her home a couple of months later.

Here is a patient in the best of health suddenly having a relapse after sputum containing many tubercle bacilli.

Spindle health since. Weight 73 kg.

tuberculin would be sufficient to set the immunization process going; on the other hand, in advanced phthisis treated with toxin, a small dose of tuberculin would be like a drop in the ocean. It is in these latter patients as such marvellous results, provided always the reactions owing to an injection are favourable and create sufficiently destroy the germs.

upon which should only be handled by men with experience. Such a treatment, in which so much depends on the active powers of the patient, and which, if used carelessly, sometimes have most deplorable results (Case 14), or even if used with the greatest care, may occasionally be of little improvement, or which (especially if very large doses are used) may greatly lessen the chances of recovery, is one not lightly to be undertaken.

shall pass over treatment by tuberculin insufflation and injection (provided the tuberculin becomes absorbed) to regulate the doses, and the risk to the patient (though the skin) as unscientific, because it would be liable to be even greater still.

### SODIUM MONTMORILLITE.

In the issue of the BRITISH MEDICAL JOURNAL of February 1919, Sir Leonard Rogers published a short article on the treatment of tuberculous by subcutaneous intracutaneous, or intravenous injections of the sodium salts of unsaturated fatty acids of cod-liver oil by mouth, which he called sodium montmorillite.

He will know the value of cod-liver oil by mouth. Patients suffering from tuberculosis. What at once would be the most in connection with this new discovery—the fact that, if successful, the effect of it would not be to depend so much on the reactive powers of a patient, that it would act directly (as Sir Leonard Rogers suggests) by dissolving the coating of these acid-fast bacilli and thus laying them open to destruction.

Having started this new treatment from the middle of 1918, and having used it since almost exclusively, I am so much impressed with the results obtained, superior in every way to other methods (Cases 18, 19, 27) used by me in the past, that I would not even withhold it from an almost any patient.

I have seen this patient on several occasions since, the last time about a week ago, and she still seems to be in perfect health. During all this time the patient lived in Sydney doing her own housework.

Case 15.—A very similar case to the last one is that of Mrs. C., who came to me suffering from tuberculous phthisis a few years ago. While T.B.K. treatment brought about only a slight improvement, treatment by sodium montmorillite was followed by a complete arrest of the disease. This patient, like the last, released after receiving a small dose of T.B.K. She is quite well now. Her two boys, suffering from tuberculous adenitis, are also in good health after treatment by sodium montmorillite.

The next two histories will show how tuberculous disease treatment can bring about an arrest of tuberculous disease even after sanatorium treatment has failed.

(Case 25)—November, 1921. Mr. S. M., aged 37 years, weight 75 kg. (height 5 ft. 1 in.). Six months. Had three months' sanatorium treatment without any improvement. Then went to the New England district (well known for its dry and bracing climate) for some months. Slight increase in weight, but at the end of the year cough, and frequent haemorrhages did not improve, he came to Sydney for further advice. Right apex, second to third stage. Sputum contained tubercle bacilli (Guérin V). Started sodium montmorillite treatment in May, 1922. In August, 1922, haemorrhages had practically ceased and sputum became clear of tubercle bacilli. I may mention that the two to three weeks after commencing treatment he resumed his work as a commercial traveller, and has continued it without a break up to date. Feels and looks well.

(Case 24)—April, 1921. Mr. A., aged 35 years, weight 65 kg. After three months' sanatorium treatment with T.B.K. no improvement, cough, etc. Right apex, third stage. Sputum contained tubercle bacilli (Guérin X) and streptococci. Diagnoses: Tuberculous phthisis. After eight months' treatment with sodium montmorillite the sputum was free from tubercle bacilli, no more haemorrhages; weight 71.5 kg. July, 1922, under the worst possible conditions. During the treatment he lived in a very unhealthy suburb with his wife and four children in very poor circumstances.

(Case 23)—May, 1920. Bro. C., aged 42 years, weight 65 kg. Suffered from frequent attacks of "sore throat" for the last fourteen years much worse the last six months with absolute loss of voice. Right apex, second stage. Cough. Latent, both local cords infiltrated with tubercle formation. Both retropharyngeal follicles swollen and ulcerated. Sputum swarming with tubercle bacilli (I do not remember a worse specimen). Diagnoses: Pulmonary and tuberculous phthisis. After two months' sodium montmorillite treatment (in Sydney) sputum free from tubercle bacilli. Two subsequent sputum examinations gave the same result. After four months' treatment weight 70.5 kg.; lung fissured and latent hoarse. As both local cords had been practically destroyed his voice will always be affected.

(Case 22)—April, 1922. M. M., aged 33 years, weight 54 kg. Abnormal gland from one of the Pacific islands. Very bad family history. Ill twelve months. Right apex, third stage. Large gland (size of a large pigeon egg) in front of right sternum-mastoid. Sputum contained tubercle bacilli (Guérin VI) and streptococci. Diagnoses: Tuberculous phthisis. Sodium montmorillite treatment. To-day gland disappeared; no lung symptoms except some dullness and irregular breathing at former site of disease. As expectoration has ceased, cannot examine sputum. No cough; weight 53.5 kg. I give this history as there were two special drawbacks: (1) Coloured people it interfered with the growth of tubercles are the most patients for treatment, (2) it is most difficult to improve children if they once develop tubercles of the lungs. In spite of this, the patient got better. If improvement will be permanent I cannot say.

(Case 21)—August, 1920. B. W., aged 22 years, weight 45 kg. Good health up to three years ago, when he became incapacitated at the front in France. Right apex, second stage. Sputum contained tubercle bacilli (Guérin II). Had two courses of sodium montmorillite treatment. To-day feels fine; weight 60 kg.

(Case 20)—November, 1920. Mrs. K., aged 60 years, weight 45 kg. Syphilis blood pressure 160. Several extremely large cervical glands at the root of the neck (both sides). Ill some time. Had been told that she had cancer, and advised to have it removed by operation. Diagnoses: Tuberculous phthisis. Sodium montmorillite treatment. In July, 1921, when a complete disappearance of these glands. Weight (July, 1922, 55 kg. (July, 1922) 60.7 kg. September, 1922, small gland left still.

(Case 19)—July, 1922. D. D., aged 45 years. Short time before coming to me had several tuberculous glands removed from the right axilla. Large swelling of right wrist and carpal bones. After three months of treatment by sodium montmorillite he was changed with the disease arrested, no sputum; weight 65.5 kg.

consideration in view of its obvious importance in relation to various tropical diseases in man and certain widespread diseases of animals.

Apart from the systematic position of the different main divisions of micro-organisms, the classification of the bacteria into families, genera, and species is one of the most confusing of our immediate problems. As in other departments of biology, the determination of species is a fundamental difficulty. While the botanist and zoologist relies on morphology as his ultimate criterion, in bacteriology physiological functions, biochemical reactions, and disease-producing properties may serve to differentiate and identify important species. In addition, the specific reaction of the serum of an immunized animal to the homologous bacterium—a criterion not employed thus in other branches of biology—constitutes one of our most delicate tests of identity. On the other hand, this finess in identification has often complicated our classification to such an extent that we hardly dare speak of "species" in bacteriology—if such a fixed entity really exists—and in certain bacterial genera biochemical and serological criteria yield the most amazing multiplicity of types. A broad system of classification is urgently required, however, and the most serious attempt in this direction is that of the Society of American bacteriologists, which has recently proposed a new classification of the bacteria. While this system is undoubtedly sound and seems to possess a convenient elasticity, it involves a revolution in nomenclature—a disadvantage to older students of the subject.

Among the bacteria it has been found possible to follow closely the process of spontaneous variation, and in this way the evolution and origin of new types can be studied. The great diversity and multiplicity of types among certain bacterial groups can thus be explained to some extent on the basis of rapid mutation.

From the purely biological standpoint the question of a bacterial life-cycle deserves some comment. It has been generally accepted that bacteria, as contrasted with the protozoa, exhibit no real life-cycle, and that their morphology is of the simplest and most uniform type. On the other hand, it has to be remembered that our knowledge of the structure of such exceedingly minute organisms must necessarily be somewhat limited. There is already a considerable amount of literature dealing with the supposed life-cycle of bacteria, and this conception has been daringly used to elucidate certain unexplained epidemiological peculiarities (for example, waves of epidemic prevalence, etc.). A further development of this idea is to presuppose changes in toxicity and virulence associated with different phases in life-history. Moreover, the question of an exceedingly minute or filtrable phase in certain recognized pathogenic micro-organisms has also been raised, and might be considered in relation to the whole problem of the filtrable viruses. Though the interpretation of many of the data in this subject justifies frank scepticism, they at least point to an interesting field for further investigation.

Within the last few years a remarkable biological phenomenon among the bacteria has been observed and studied, the so-called Twort-d'Herelle phenomenon—that is, the lysis of bacteria by some active principle transmissible from generation to generation of a bacterial culture. D'Herelle has elaborated the somewhat startling idea that the lytic effect is due to an ultramicroscopic parasite of bacteria, or "bacteriophage," which actually reproduces itself within the bacterial cell. It would thus fulfil the old postulate verified by Swift that even a small parasite has its own lesser parasites. The biochemical explanation that the active principle is an autolytic enzyme of bacteria, and that its apparent transmissibility and reproduction are not necessarily due to a separate living organism, is perhaps the more acceptable theory.

There is no lack of scope, therefore, for the purely biological investigation of the bacteria, and at the present time it might appear that the study of the fundamental biology of these micro-organisms has perhaps been sacrificed in the past to the more attractive investigation of their direct relation to disease and the everyday affairs of mankind.

#### ETIOLOGICAL CONSIDERATIONS.

Bacteriology, though primarily a purely biological science, owes most of its actual development to the modern study of pathology, for its importance in medicine must always depend on the essential fact that it deals with the genesis of a large number of diseases. The majority of deaths among our own species are attributable to microbic infection, and certain prevalent diseases of still unknown etiology may yet be shown to be due to micro-organisms or their toxins.

I have referred to the great discoveries of the latter part of the nineteenth century which brought to light the causal agents of many prevalent diseases—the discovery of the typhoid bacillus, the cholera vibrio, the diphtheria bacillus, the tubercle bacillus, and many other pathogenic micro-organisms in rapid succession. The etiology of various diseases was thus explained in what seemed at first to be a relatively simple manner; but the identification of the causal agent has not always elucidated every problem in the particular condition.

Disease is a complex process dependent on several factors, and in even a well defined infection the invading micro-organism, though the specific and essential cause, is not the only factor that determines the process. It is futile to study a parasite apart from its interaction with the host and without regard to the passivity or antagonism of the latter, and also the external influences that affect both.

While the achievements of bacteriology in elucidating disease have been of almost unequalled value in medicine, serious obstacles still confront us in the fuller application of our science. Granted that all infective diseases are of microbic origin, there are still many obvious infections whose causal agent remains undetermined; but we have to remember that it is not so many years ago in this present century since the *Spironema pallidum*, the organism of syphilis, was observed for the first time, and it is only within the last few years that the leptospiras of infectious jaundice and yellow fever, and other previously unknown pathogenic micro-organisms, have been described. Bacteriology was alluded to in 1918 by one of the leaders of our profession (Sir Clifford Allbutt) in pointing to possible now conquests in other branches of medical science, as a "territory—largely won," but I can assure you we have only passed the frontiers, and there is still great scope for conquest in this department of science. Consider, for example, the bacteriological problem in leprosy: the leprosy bacillus was first described about fifty years ago by Hansen, and to anyone approaching the study of leprosy for the first time the problem might seem one of the easiest to solve; but in spite of repeated studies of this organism little is yet known of its biology and experimental pathogenesis. Without this knowledge definite information cannot be obtained as to the transmission of the disease and immunity to the infection—important practical questions in countries where leprosy is prevalent. In fact, the bacteriological difficulty in this infection is almost unparalleled; no other obvious bacterium occurring in such enormous numbers in the lesions of the disease has proved so resistant to artificial cultivation. The majority of attempts to obtain cultures for experimental study have been unsuccessful, and where success has been claimed the results are still open to doubt. When a fundamental problem still remains unsolved with regard to a micro-organism so easily demonstrable as the leprosy bacillus, it is not difficult to appreciate the obstacles still to be overcome in demonstrating less obvious microbic agents and in proving their pathogenicity beyond a shadow of doubt.

The pioneer work in bacteriology brought into rapid subjection certain groups of micro-organisms which now yield many of their biological secrets to our ordinary technique, and diseases due to such organisms have been investigated bacteriologically with most valuable results as regards diagnosis, prevention, and even cure. There still remain a large number of prevalent infections in which a microparasite has proved less easy of demonstration—where the customary technique has been quite ineffective. The *Spironema pallidum* long remained refractory to microscopic observation until special methods had been

elaborated for the purpose, but at the present time this organism yields easily to a specialized technique; and so it may be with certain other pathogens.

For a good many years now active studies have been steadily proceeding, which first raised the question of an "ultramicroscopic" type of organism minute enough to pass through the pores of a porcelain filter, and therefore designated "filtrable virus." Proof that these viruses represent living organisms was established by experiment, and many prevalent human and animal diseases were shown to be due to such agents—for example, rabies, epidemic poliomyelitis, rinderpest, etc. More recently, attempts to cultivate them artificially have in certain instances proved successful, with the result that some information is now directly obtainable regarding their biology. It seems unlikely, however, that all the viruses of this nature represent a homogeneous biological class.

It is interesting to recall how, a number of years ago, the virus of yellow fever present in the blood of infected persons was found to be filtrable and it was classified as ultramicroscopic. In 1919, however, Noguchi described as the causal organism of the same disease a leptospira whose etiological relationship to yellow fever is now generally accepted. The filterability of the virus was also confirmed by Noguchi, and the possibility of a granular phase of the leptospira such as that described in the case of other spirochetes was suggested. All these facts are of the greatest significance in relation to the whole question of the biology of the filtrable viruses, but hasty generalizations and speculations are to be avoided.

The influenza problem also exemplifies the intricate difficulty of determining the exact causal agent of an obvious infective disease. Since the pandemic of 1918 bacteriologists have been divided in opinion as to whether the classical *B. influenzae* of Pfeiffer or a filter-passing virus is the primary causal agent in the disease. Without treading already well worn ground in this controversy, attention may be drawn to the successful isolation of an exceedingly minute bacilloid filter-passing organism from this disease by independent workers in different countries—the *Bacterium pneumosintes* of Olitsky and Gates. Having had the opportunity of studying the biological characters of this organism (isolated by Sir Spencer Lister), I have little doubt of its close relation to the true bacteria; its size is not constant and in a certain environment it may attain the dimensions of one of the recognized bacteria. These facts are also highly significant in any biological speculations regarding the filter-passing organisms. The "Rickettsia bodies" of typhus fever and the "globoid bodies" of epidemic poliomyelitis provide further examples of exceedingly minute structures of doubtful biological nature that have to be reckoned with in the new bacteriology.

The whole subject of the filtrable viruses is a field of study in which a vast amount of careful investigation is required and it holds many pitfalls for the unwary observer; but here we must look for some of the conquests of the future.

The present position, then, in the etiology of infective disease is that a large number of infections are due to, as it were, tangible micro-organisms, but in a considerable proportion of prevalent diseases admittedly infective, the causal microbe is either quite unknown, or doubtful, or still undefined in the biological sense. I need only quote, to exemplify this, such human diseases as small-pox, measles, scarlet fever, and rheumatic fever, though we have a large volume of highly suggestive observations bearing on their causation.

While in medical bacteriology a single specific organism is the usual objective, we cannot disregard the fact that the sum-total result in an infective disease is not always the product of one parasitic species; micro-organisms may and do attack the tissues in team fashion. In certain of those processes due to saprophytic bacteria that go on in nature, it is generally agreed that the changes cannot be interpreted as a function of one species acting alone but of two or more flourishing together in symbiosis. This must not be overlooked when investigating the causation of microbial disease. Studies of dysentery have shown that a specific dysentery bacillus may only be the starter of the process and

that special concomitant bacteria may aid and abet the other (Mackie). The same is true for other conditions. An interesting example of a concomitant organism is seen in actinomycosis, long recognized as due to one of the higher bacteria, the actinomyces; in most of the cases that have been fully investigated the actinomyces is found to be associated with another organism of apparently different order which can be grown quite independently (*B. actinomycetum comitans*). The full significance of such concomitant infections is somewhat obscure and requires further elucidation.

The selective affinity that different bacteria possess for particular animal tissues is also an important etiological factor, and it has been shown that within the same species there may be separate types differing in their tissue selections. This is of the greatest significance in the pathology of certain infections: for example, dermatrope and neurotrope types respectively of the syphilis virus have been recognized, the latter being the responsible agent in syphilitic disease of the central nervous system. On the other hand, as shown by animal experiment, the virus of herpes may also produce encephalitis—thus two diverse types of lesions in different tissues may be due to the same agent (Levaditi, Kling).

Apart from exogenous infection due to micro-organisms that have usually no place in the body of the healthy animal, those commensal microbes which normally inhabit the surface of the body and certain body cavities represent a constant menace to the tissues. Exogenous pathogens, however, may gain access to the body and for a time assume a commensal rôle without tissue invasion and pathological effects.

These facts all indicate the extreme complexity of the etiological problem.

#### IMMUNOLOGICAL CONSIDERATIONS.

The study of immunity (immunology) is inseparably bound up with bacteriology and pathology, though at the present time it has practically attained the position of an independent science. Well defined principles have been established which have stood us in good stead from the practical standpoint, but the general tendency of recent research has been to demonstrate the complexity of the underlying biological processes, and now we are being confronted with new principles and new theories often subversive of the older ideas. The original work on immunity, however, elicited facts and phenomena which are still incontrovertible, and the artificial production of immunity for prophylaxis and treatment will ever be one of the greatest achievements in the history of medicine. The early scientific work on artificial immunity almost seemed to herald a glorious future in which infective disease could be easily overcome; the antitoxin treatment of diphtheria revolutionized the therapeutics of this disease; Pasteur's hydrophobia vaccine minimized the terrors of rabid dog bites; typhoid vaccination has reduced the great prevalence of typhoid among armies in the field; tetanus antitoxin used as a prophylactic has obviated many a death from this fatal disease; small-pox vaccination has contributed to the removal of that epidemic scourge of past times, and it is to be hoped that the lessons of the past will not yet be entirely forgotten. But many natural obstacles have barred the universal application of this means of prophylaxis and treatment. Unfortunately immunological therapy has not always been employed in a rational or scientific manner, and certain measures of this type, not fully justified by the general value of the results obtained, have been exploited to such an extent that the whole system has often been in danger of discredit.

Attention has been drawn quite recently to a possible obstacle in artificial immunization against certain types of bacteria—for example, the tubercle bacillus: that these organisms possess fatty envelopes which prevent their proteins from coming into contact with the tissue cells and so stimulating an immunity response when injected in vaccine form (Dreyer). If the removal of this obstacle is ultimately proved beyond doubt to allow of effective immunization against such bacteria, medicine will owe a great debt to this immunological achievement.

One of the great principles of antibacterial immunity has

Dec. 29, 1923]

THE TREATMENT OF LEPROSY BY COLLOIDAL ANTIMONY HAS BEEN  
 A TRIAL IN THE ISOLATION HOSPITAL (OPPENHEIMER) AT BAGHDAD. OUR EXPERIENCE MAY BE INTERESTING TO OTHERS. THE TRIAL EXTENDED  
 OVER A PERIOD OF NINE MONTHS, BUT PATIENTS WERE USUALLY  
 TREATED WITH THIS PREPARATION FOR ABOUT THREE MONTHS,  
 AND THE RESULTS ARE COMPARED WITH THOSE FROM THE INTRA-  
 VENOUS INJECTION OF A MIXTURE OF CHLAMOXYDRA OIL AND  
 OTHER IN THE SAME PATIENTS. FIFTEEN CASES WERE TREATED,  
 IN ALL OF WHOM THE DIAGNOSIS WAS CONFIRMED BACTERIO-  
 LOGICALLY. ALL THE CASES WERE SEVERE AND WERE UNABLE TO  
 WORK. THE TYPES WERE NODULAR, MACULAR, AND ANAESTHETIC.

It is precisely in this direction that promise is afforded by Dr. Boekke's plan of giving small subcutaneous doses of freshly prepared solutions—a point I believe to be of great importance—such doses as do not produce local reactions at the site of injection, which appears in her hands to have eliminated the dangerous general reactions sometimes following the larger intravenous doses formerly advised by me on the basis of their effectiveness against the much less toxic acid-fast bacillus of Depress. The new method of administration, if confirmed by trials now being carried out by experts in this and other countries, may furnish a safe, simple, and exceedingly cheap method of treating at least a fair proportion of tuberculous cases, although prolonged observations will be necessary before the precise indications for its use can be worked out.

Dr. P. W. L. Boekke for kindly sending a copy of her paper, and regarding both the method of administration and the results obtained as of great importance for the following reasons. The first trials of specific vaccine reported by me in 1919<sup>1</sup> established its specific action on tuberculous disease, as shown by febrile reactions with swelling of the tuberculous glands, and more widespread ulcerations of the tuberculous sinuses due to an increase in the effects that may be followed by improvement. Recently Dr. Boekke's interesting observation of local reactions at the site of subcutaneous injections of the drug in tuberculous cases confirms its specific action on this disease. Her observations are, however, of excessive gain for the past year's progress in the treatment of tuberculous diseases, and in one case of disseminated dermatitis, it was followed by the use of intravenous doses, and the following observations are of great importance, although the very fact that it is not necessary to inject it in tuberculous cases is a great advantage. It is to be hoped that it will be kept within state hospitals on tuberculous tissues indicates that it is very necessary to be careful action, if this can only be kept within state hospitals.

*Sodium Morthate Treatment.*—Three per cent. solutions, to which 5 per cent. carbolio acid had been added, were used after sterilization in an autoclave. Solutions, which should be clear or become clear on reheating, were made up fresh once or twice a week. In four children doses were diluted by one-half. Starting doses for subcutaneous or intramuscular injections were 1 c.c.m., and increased by 0.1 c.c.m. (provided no reaction followed, when the dose was either repeated or lessened), to 1 c.c.m. or a little more. At intervals of three to five days, larger doses were usually repeated at intervals of six to seven intravenous injections up to 3 and 4 c.c.m. in a few cases did not seem to give any better results than the repetition of 1 c.c.m. doses.

been that the immune state is due to specific serum antibodies which have an adverse influence on the particular organism or neutralize its toxin, and passive immunization by the injection of the serum of an immune animal, which has undoubtedly proved of the greatest value in certain conditions, is based on this. The study of these antibodies is one of the most fascinating in the whole field of scientific medicine and its range now extends far beyond strictly bacteriological limits. In short, antibody development constitutes an important demonstrable reaction of the tissues to the introduction of any alien protein, and the specificity of antibodies for the particular type of alien substance (antigen) is one of the most remarkable of biological phenomena. It is more than doubtful, however, if these reactions constitute the complete immunity mechanism of the body. The tendency may have been to attribute immunity to phenomena observable by known laboratory methods, but present knowledge is now revealing the existence of still unknown factors. Immunity may exist in the absence of "immunity reactions," and it is open to question whether certain antibody effects signify an immune state. It has been shown that particular tissues may be locally immunized to certain bacteria without any general reaction (Besredka). Moreover, we now know that the resistance of the tissues may be influenced in a non-specific fashion by the parenteral injection of alien protein, and it is difficult sometimes to disentangle in our interpretation of results the specific from the non-specific effects when an alien protein substance is injected into the body for immunization purposes—for example, an immune serum or a vaccine consisting of killed bacteria. The possibility that one infection may influence the resistance of the tissues to another is already supported by experimental and clinical experience. We find also that an endocrine secretion, adrenaline, may play a part in the immunity mechanism and render innocuous certain bacterial toxins—for example, that of the diphtheria bacillus (Marie). Finally, it must be borne in mind that while the interaction of antigen and antibody may under one set of conditions lead to immunity, under another set the very opposite effect—anaphylaxis, or hypersensitiveness—is produced.

Thus the scope of immunology has been gradually widening, and the solution of many of our problems must ultimately depend to a large extent on a fuller knowledge of the underlying chemical changes in the tissues on which immunity depends and of the chemistry of the reacting elements and the chemical and physical nature of the reactions. In laboratory immunological work we observe and utilize reactions in which we still know comparatively little about the fundamental chemical and physical phenomena. The reacting substances are apparently colloids—the "dynamical state of matter" (Graham)—and the reactions may only be elucidated by further reference to colloid chemistry.

I have referred to the high degree of specificity of serum antibodies; in virtue of this certain antibody reactions play an important part in the diagnosis of infections. The classical example is the Widal reaction, which depends on the *in vitro* clumping or agglutination of the typhoid bacillus by certain antibodies (agglutinins) in the serum of an infected person. Similar tests have been employed in other bacterial infections, but at the present time their limitations must be emphasized as well as their value. Antibody development in infection is inconstant both in degree and time, and such variations must be reckoned with in this method of clinical diagnosis. Moreover, the serum of a normal person is not always without agglutinating properties, especially for certain bacteria, and the quantitative limits of normal effects will determine what is a significant diagnostic result. This has been particularly true in the serum diagnosis of Malta fever.

One of the most unexpected developments of recent years in this field is the so-called Weil-Felix reaction, which depends on the agglutination of a certain type of *B. proteus* by the serum in typhus fever. In this disease antibodies are developed that are specific for an antigen which, as far as we know, has no etiological relationship to the particular disease. These so-called "heterogenetic" antibodies present further interesting complexities to the student of

immunity. The Wassermann serum reaction, which was discovered in almost a fortuitous manner, is probably to be regarded also among these obscure heterogenetic phenomena. Even the apparent anomalies in immunity have, therefore, rendered service in practical medicine.

Antibodies are specific for the biological species, and antibody reactions have therefore become criteria of species; but this specificity may be more restricted and has often revealed profound differences in the immunological characters of different strains of the same species. This knowledge has had an important bearing on artificial immunization. Among the pneumococci, for example, a number of different immunological types can be recognized. Immunization against one would not confer immunity to another, and for prophylactic vaccination against epidemic pneumonia all types must be represented in the vaccine used. This system has yielded most valuable results in combating pneumonia among the native labourers in the gold mines of South Africa (Lister); at one time this epidemic disease seriously threatened the gold mining industry in that country.

The recognition of different immunological types among certain pathogenic bacteria has influenced immunological measures both for prophylaxis and treatment and has overcome to some extent one of the obstacles in the way of applied immunity.

#### THE MECHANISM OF MICROBIC ATTACK ON THE TISSUES.

For many years we have spoken of bacterial toxins, we have prepared toxic substances artificially from bacteria, we have utilized them for immunization, studied their experimental effects, classified them and so on, but this work has generally aimed at demonstrating some specific poison in artificial culture of bacteria. In some cases it has been apparently successful and substances have appeared in culture which, apart from the bacteria themselves, can reproduce the particular disease in animals. In other cases no specific poison can be prepared. These so-called toxins, however, have never been isolated as pure substances. By reference to the biochemistry of the saprophytic bacteria the most elaborate chemical changes produced by these organisms in nature are interpreted in terms of enzyme action. In explaining the mechanism of disease production by microparasites, according to Pasteur's original conception, the ultimate interpretation of the tissue changes, which are fundamentally chemical, must be on similar lines; but in addition to the microbic ferments acting on the tissues, there is the reciprocal effect of the tissue enzymes to be reckoned with. Even the specific toxins show a close though not exact analogy with the ferments.

In this study new lines of thought and experiment have been indicated by Vaughan, who conceives the whole chemistry of infective disease in terms of protein decomposition by ferment action and the liberation of a protein poison or poisonous atom group of the protein molecule which is active in virtue of its intense chemistry. The toxic principles in infective disease are not necessarily direct products of the parasite in the same way as poisonous chemicals are directly elaborated by plants.

New ideas regarding the mechanism of infection must be reflected in our conceptions of immunity, and at the present time there is the most urgent need for marshalling all the valid data with a view to their co-ordination. Otherwise our knowledge is in danger of becoming simply a chaos.

#### REGARDING CHEMICAL AND PHYSICAL INFLUENCES ON MICRO-ORGANISMS.

The adverse chemical and physical influences that can be artificially brought to bear on micro-organisms have proved an attractive study, and the results have provided important practical applications not only in general disinfection but also in the therapeutic elimination of organisms from the tissues. Certain therapeutic substances of the present day are the direct product of this study (salvarsan in the treatment of syphilis) and there is great scope for chemotherapeutic investigation. The primary aim in this work is to identify chemical compounds with the maximum germicidal power for particular micro-organisms and the minimum toxicity for the tissues—a combination not easy of fulfilment.

The bactericidal action of light is one of the most remarkable of natural phenomena. It has been generally agreed that it is due to the ultra-violet region of the spectrum, but recent investigations have shown that certain parts of the visible spectrum, particularly the red region, are powerfully inhibitory and even lethal to various bacteria (Van der Linden and Mackie; unpublished observations).

#### THE INFLUENCE OF THE WAR ON BACTERIOLOGICAL SCIENCE.

The war both emphasized problems and necessitated their expeditious solution. War conditions also, with the inevitable prevalence of infection among armies in the field, provided large collected masses of material for the study of individual diseases. The concentration of troops in various tropical and subtropical parts of the world with the occurrence of infective diseases characteristic of these regions greatly widened the range of study, and British bacteriologists were enabled to investigate etiological, diagnostic, and immunological subjects that normal conditions in Great Britain would never have provided. The result has been a significant gain to pathology and bacteriology, and out of the welter of war has come a further justification of scientific medicine.

The value of antityphoid vaccination was one of the earliest results to be noted, though in the Near Eastern campaign a by no means negligible loss was due to the initial overlooking of paratyphoid fever as a prevalent infection in the East. This omission was rectified by the use of the combined typhoid-paratyphoid vaccine, and after 1916 the incidence of the enteric fevers became practically minimal.

The great war also proved beyond doubt the prophylactic value of tetanus antitoxin, and this immunological application alone contributed something to alleviating the horrors of war.

Dysentery, both amoebic and bacillary, was studied in a truly exhaustive fashion: in fact few individual infective diseases have ever been so extensively investigated. New types of causal organisms were observed, methods of laboratory diagnosis were perfected, and certain systems of treatment were carefully evaluated. On a smaller scale choleraic disease attracted a certain amount of attention among army bacteriologists in the East, and the occurrence of paracolera was established—that is, choleraic illnesses due to vibrios specifically different from the classical cholera organism and of different epidemiological significance (Mackie).

The war also brought to light a previously unknown disease, designated by the historic and significant name of "trench fever." The infective nature of this condition was clearly proved, and later work which showed it to be louse-borne indicated means of prevention. The question of the microbic agent, however, provides a further instance of the difficulty of demonstrating and defining the infecting organism in certain diseases. The presence of the organism in the blood was proved indirectly by experiment, but it cannot be said that microscopic examination ever clearly revealed a definite parasite, and the virus was not of the filtrable type. It was shown that the excreta of lice which had fed on the blood of persons suffering from the disease were infective and contained certain minute bodies with recognizable characters but smaller than the ordinary bacteria—the so-called "Rickettsia bodies"—and though there is strong evidence that these represent the causative microbe, the final proof is still wanting and their biological nature remains uncertain.

Many other important data of outstanding practical importance were obtained during the war period. These have contributed much to our present knowledge of bacteriology and are now reflected in laboratory and clinical methods. They are well exemplified by the work done on epidemic cerebro-spinal meningitis, infectious jaundice, malaria, the venereal diseases, gas gangrene, etc. The period of the great war will always be a memorable one in the history of medicine, and bacteriology may justifiably claim a signal share in the medical and surgical triumphs of that epoch.

#### THE STUDY OF BACTERIOLOGY IN THE UNIVERSITIES AND MEDICAL SCHOOLS.

The observations I have made, scanty though they be, all go to show the need for a continued and even more vigorous

attack on disease by microbiological methods. In equipping the necessary personnel for this offensive and in the ordinary medical training, the question of bacteriological teaching in the medical schools merits some consideration.

During these times of reconstruction most careful attention has been given to the subject of medical education, and existing systems have been revised in the greatest detail. The trend of development in medicine towards scientific application demands that the student should obtain as complete a scientific education as possible; but the possible scope of science teaching in medicine is an exceedingly wide subject, and in any case it is obvious that no undergraduate education could compass a full training in all the medical sciences. Whatever education the undergraduate receives can only be an introduction to a wider experience and a fuller knowledge.

Among the medical sciences bacteriology offers an attractive and educative field of study as a biological and applied science, though it is only one branch among many of medical training and research. In the past the training in this subject given to the undergraduate in this country has been for the most part a product of pathological teaching, and at the present time the correlation of pathology and bacteriology in the curriculum is still ideal and essential in the interests of both subjects; but bacteriology now provides so many methods of direct application in clinical diagnosis and treatment and in preventive medicine that an adequate though elementary course must now hold an essential place in any curriculum. The Education Committee of the General Medical Council in a recent attempt to systematize medical teaching recognized this, and in its draft curriculum placed this course as a preliminary to the regular clinical training of the student as a clinical clerk and surgical dresser. In short, some fundamental knowledge of microbiology is an absolute essential now to the practitioner of medicine, for he is constantly called on to approach the bacteriological problem in the causation, diagnosis, and treatment of disease. He need not carry out the investigation to a conclusion—that will usually be delegated to laboratory specialists—but on the practitioner will always fall the responsibility for initiating these procedures, and he must be in a position to appreciate the significance of results reported to him. The undergraduate course, therefore, may not convey any elaborate training, but it must impart a sound knowledge of fundamental facts and principles and a reasonable understanding of methods and procedures, with, in addition, a practical knowledge of those methods which are within the scope of the general medical worker. With only a microscope and a few simple implements and materials a vast amount of valuable diagnostic work can be done, and this is particularly true for certain parts of the world—and I can speak from personal observation—where various microbic diseases are very prevalent and where the practitioner is thrown back on his own resources without the immediate aid of laboratories.

Our aim, therefore, in bacteriological teaching, as far as the undergraduate is concerned, is to convey the theoretical and practical knowledge that will assist him to a better understanding of disease and may be necessary for the purposes of ordinary medical practice. Special or advanced knowledge of the subject and its technique can only be acquired by more intensive practical courses such as those prescribed for certain post-graduate qualifications in public health, tropical medicine, psychiatry, and for the training of special workers in this branch of experimental medicine.

Apart from human and veterinary medicine and agriculture, little provision has hitherto been made in the universities for a training in bacteriology as a purely biological science. Its increased importance at the present time makes its inclusion among the various subjects for a science degree eminently desirable, and it is gratifying to find that this has already been recognized in our University. The recent institution in an English university of a post-graduate course and diploma in bacteriology marks a further development in bacteriological teaching, and the course of training prescribed aims at providing a thorough general knowledge of the subject and also a special acquaintance with certain of its practical applications.

1255  
[MUSEUM OF THE  
SMITHSONIAN INSTITUTION]

CONCLUSION: A PLEA FOR BACTERIOLOGICAL STUDY  
AND RESEARCH.

In putting before you certain aspects of the present position of this branch of science, my aim has been to indicate that bacteriological knowledge, though already advanced to a prominent place in the forefront of human progress, still presents so many crucial problems that its further advancement must be continuously maintained. Effective teaching is vital to the progress of a science, and the student must be taught in the research atmosphere if he is to gain any real inspiration from his studies. In these respects the universities, as apart from the purely research institutes, present the ideal conditions for the advancement of science, and therefore, in inaugurating my work in this historic seat of learning which has contributed an important share to the world's stock of knowledge, I would venture to make an earnest plea for the fullest possible encouragement of bacteriological teaching and research, both in the immediate interests of medicine and in the greater and wider interests of human welfare.

SANITARY ADVANTAGES OF SOCIAL  
AMENITIES.AN ADDRESS DELIVERED BEFORE THE METROPOLITAN  
COUNTIES BRANCH,

BY

CHARLES SANDERS, M.B.LOND.,

MEDICAL OFFICER OF HEALTH AND SCHOOL MEDICAL OFFICER, WEST  
HAM; PRESIDENT OF THE BRANCH.

THE County Borough of West Ham, which I have the honour to serve, is situated on the River Thames, but I doubt whether most of the members of the Branch, if given a drawing of its sinuous curves between Richmond Lock and Hurry Fort, could place the borough in its correct position on the river bank, or could accurately describe its chief characteristics. Unkind folk have alleged that West Ham is readily recognized—witness the patronizer of the Belle steamers, plying in the summer between Fresh Wharf and Margate, who said he knew when he passed Silvertown by the row of chimneys belching forth black smoke; and there is a fairly authentic legend of an elegant young lady who, when the train came to a standstill in a thick fog and her mother said, "I wonder where we are," replied, "Oh, we are at Stratford; I can smell Pa's factory."

It will be my endeavour to enlist interest in the past history of the district—which, thanks to the patient labours of Katherine Fry, who with her eminent sister Elizabeth Fry lived there for many years, has been studied and placed on record—and to consider what bearing, if any, the changes that have occurred may or may not have had on the present-day problems of the inhabitants.

The River Lea, which separates the counties of Herts and Middlesex from Essex, and the River Roding some four and a half miles to the east, which enters the Thames near the ancient town of Barking, enclose, with the River Thames and the southern border of Epping Forest land, a quadrilateral area now occupied by the county boroughs of West Ham and East Ham, but formerly covered by the great Essex forest with some arable pasture and extensive marshes bordering the royal river. It is not surprising that Roman remains have been discovered, as the vicinal way passed through or a little to the north of the area, and Boadicea, Queen of the Iceni, who laid London in ashes A.D. 61, probably brought her forces through the same route.

One of the earliest references to the district occurs in connexion with the burial of St. Erkenwald, Bishop of London, who died at Barking Abbey in 685 while on a visit to his sister St. Ethelburga, the first Abbess. Visitors to Epping Forest even now in the height of summer can occasionally find themselves in a morass unexpectedly, and extensive floods from the swollen rivers before mentioned are still a burden to the district, and it would appear that an exceptional storm interrupted the passage of the Bishop's corpse on its journey from Barking to St. Paul's. A later writer,

gifted with greater love of the miraculous than of scientific investigation, records how

"All the people kneeled down and prayed devoutly and as they were in prayer they sawe the water divided lyke as it did to Moyses in the Red Sea and to the children of Israel goyng through into the deserte. In lyke wyse God gave a drye path to the people of London for to convey this holy body through the water to the Cytee and anon they took up the body with great honour and reverence and by one assent they hurried through the path, the water standyng up on every syde and so they came to Stratforda and set down the bere in a fair mede full of floures."

Every schoolboy knows how King Alfred in 895 stranded the ships of the Danes at Ware by cutting channels so as to divert the course of the River Lea, but few who cross them know that there are four streams passing through Stratford from a bend in the Lea which are traditionally the enlargement of Alfred's original undertaking. On this point it would be waste of time to argue with a Stratford man.

By the Domesday Book we learn that the quadrilateral area mentioned was labelled Hamme, and was, prior to 1066, in the ownership of two Saxon freemen, Alessan and Leured, but soon after that fated year passed into the possession of two Norman Barons, Ralph Peverell and Robert Gernon. Little is known of the after-history of these worthies, but during the next two centuries the chief family connected with the district was that of Montfichet, which possessed extensive lands in Essex, including several manors in Hamme. Originally from the neighbourhood of Cerisy in Normandy, a Sire de Montfichet accompanied and aided William the Conqueror at the battle of Hastings. According to Stow he appears to have built "Montfiquet's Castle" a little to the west of Baynard's castle at Blackfriars, and to have been among the hunters in the New Forest when William Rufus was shot. Either he or his son came into possession by marriage, for in 1134 William de Montfichet II was a capital lord of Hamme, where he established the Abbey of Stratford Langthorne, endowing it with his demesne and two mills near Stratford Causeway. The most redoubtable member of this family was the last of his line, Richard de Montfichet II, who was a minor when his father died in 1202, but is named by Stow along with Robert Fitzwalter and Robert FitzRoger as "three most forcible and valuable Knights of England." He was one of the twenty-five Barons chosen to enforce the observance by King John of Magna Charta, was Sheriff and Forester of Essex, Governor of Hertford Castle, and assisted Henry III against Louis VII of France, and on more than one occasion against the turbulent Welsh. He died childless in 1267 and was buried in St. Paul's Cathedral, his extensive possessions ultimately being divided among the descendants of his three sisters, and what remained was subsequently acquired by smaller landowners, because by this time the greater part of West Ham had become the property of the monks of the Abbey of Stratford Langthorne.

In the meantime Queen Maude, wife of Henry I and daughter of Malcolm Canmore, King of Scotland (an additional title inserted for the benefit of Scottish members of the Branch), had suffered while crossing the Lea at Old Ford a similar disaster to that which befell the cortège of St. Erkenwald, and to avoid a repetition she constructed what is reputed to be the first bridge built with a stone arch in England at Bow, a second bridge over the Channelsea stream, and a causeway between the two. These bridges and causeway not only proved a great benefit to Hamme but also to London, which derived much of its food supplies, garden produce, potatoes, and especially flour from the several mills at Stratford, but they became a source of much contention and litigation from the time of Henry II to Queen Victoria. Queen Maude placed the maintenance and repair of the bridges and causeway in the hands of the Abbess of Barking, endowing them with certain lands and a mill. The Abbess transferred her trust, at his request, to the Abbot of Stratford Abbey on its foundation. Subsequent Abbots constantly neglected their responsibilities until forced by the courts to comply, and after the dissolution of the Abbey on March 18th, 1538, subsequent owners of what had been Abbey lands endeavoured to avoid their liability for the necessary repairs or for paying the Abbey land rate. The upkeep was finally taken over by the local board in 1876 (for a consideration), so that visitors who now motor to

glandular infection has become extra-  
 s impossible to gauge the extent of the  
 presence of the ill defined and more  
 iration. Cases such as these, if operated  
 responsible for the mortality, due to  
 or early haemorrhage from some large  
 ds show sixteen deaths from operation,  
 from haemorrhage; this, however, is far  
 the total mortality. Recurrence took  
 about 20 per cent. of the operated cases.

# NOT OF GENERAL PARALYSIS OF BY MALARIAL INFECTION. (Preliminary Note.)

observation that had been made from  
 1816—namely, that cases of dementia  
 active encephalitis or general paralysis of  
 nity showed prolonged remissions and  
 following a febrile illness or protracted  
 ver-Jauregg's in 1909 began a series of  
 treatment of certain degenerative  
 current infections. After preliminary  
 ill and various vaccines, in 1917, he  
 1030-1050 F. during the febrile stage; the last four or five  
 attacks were usually not so severe, the maximum tempera-  
 ture becoming progressively lower. Although the malarial  
 as potent for the purpose of transmission after the four-  
 teenth case as at first. Following the termination of the  
 malarial period, noranospholium was given intravenously  
 in full doses (0.9 gram) at weekly intervals for six weeks.

1921, the patient first began to have difficulty with regard to  
 speech. When first seen (August 25th, 1922) he complained of  
 headache and insomnia and difficulty in articulating certain words.  
 Moreover, he was easily agitated, talkative, laughed inappropriately  
 out adequate cause, and had a high opinion of his accomplish-  
 ments, in spite of the fact that he was unable satisfactorily to  
 carry out his duties as a school caretaker.  
 Physical Signs.—Pupils: right eccentric and sluggish to light;  
 left normal. Lingual and labial tremors. Knee-jerks and ankle-  
 jerks brisk; plantar flexor. Wassermann reaction: blood  
 positive; cerebro-spinal fluid, 21 cells per cubic millimetre.  
 Globulin and Wassermann reactions positive. Colloidal gold test  
 positive; parvex curve.

## CASE 1.

these cases are as follows:  
 do for some weeks prior to treatment. Brief details of  
 recently treated continues at work that he was unable to  
 able, and both have returned to work. Another case only  
 provement; in two cases the improvement has been remark-  
 insane treated, all but one exhibit varying degrees of im-  
 Of the twelve early cases of general paralysis of the  
 in full doses (0.9 gram) at weekly intervals for six weeks.

Brentwood or Southend need not concern themselves with doubts as to the substantial character of the causeway between the Lea and the Channelsea, but they might profitably remember the virtues of good Queen Maude.

In Queen Elizabeth's reign our population grouped itself into three villages—a central one between the parish church and the site of the Abbey, a straggling hamlet round Stratford Green in the main Essex road, and a pleasant pastoral colony named Plaistow near the southern marshlands. The monks during their four hundred years' residence had established a trade with Italy in wool, while Stratford from its favourable situation and the numerous mills on the water-courses had long been famous for its bread-making, a trade largely carried on by the fair sex, for we read, I regret to say, of many bakeresses being fined for giving short weight, while, according to Stow, John of Stratford in the fourth year of Edward II, for making bread less than the assize, was with a fool's hood on his head and loaves of bread about his neck drawn on a hurdle through the streets of the city. The Earl of Leicester fixed upon Stratford as a suitable lodging for the Virgin Queen at the time of the Armada, but Her Majesty preferred to visit her troops at Tilbury by river trip. She possibly remembered a previous visit to the district when, as Miss Strickland tells us, in the youthful charms of her twentieth year she accompanied her step-sister, who was nearly double her age, from Wanstead to London on the occasion of Queen Mary's accession—a prelude soon to be followed by Elizabeth's incarceration in the Tower.

Under the Stuarts and the Hanoverians the district was largely devoted to sheep-farming and market gardening, being specially noted for its potato crops; while at the same time it grew in favour with the wealthy citizens of the metropolis as fashion prescribed a country residence, so that many handsome mansions, surrounded by gardens and coverts, were dotted throughout its area. Unfortunately the proximity of the Forest offered exceptional opportunities for highway robbery, and West Ham afforded domicile during some period of their depredations both to Henry Cook, who doubled the characters of highwayman and shoemaker at Stratford and was hanged in 1741, and to the more famous Dick Turpin, who was apprenticed to a butcher in Plaistow, was hunted from his fastness in Epping Forest, and ended his career on the gallows at York in 1739. Possibly both these evil-doers on occasion consulted Dr. Samuel Jebb of Stratford, the father of Sir Richard Jebb, Physician in Ordinary to George III. Opinions will differ as to whether it is a mere coincidence or a natural consequence that the locality which once harboured Dick Turpin now contains many firm believers in the Capital Lery. As a set-off we lay claim to distinguished past residents in the persons of the Duke of Somerset, Protector during the minority of Edward VI; of Edmund Burke, who lived some time in Balaam Street, Plaistow; and we are still the proud possessors of Upton House, in which Lord Lister was born (1827).

When Queen Victoria came to the throne the population had not reached 12,000, but in 1847 the Eastern Counties Railway established their works in the northern part at Stratford, and in 1866 the Victoria Dock was constructed in the south; there followed rapid increase in factory building, congeries of streets and swarms of people, changing in fifty years a rural arcady into a busy manufacturing town, the growing areas extending from north and south as from two epiphyses, to join with what was originally the main central village.

It would be interesting to know the sanitary conditions affecting the population during the various phases of the past, but the indications afforded by the scanty records that remain lead one to conclude that, despite its reputation for sylvan amenities, the district did not escape epidemic disease. During the great plague West Ham, like other country districts, was considered a haven of refuge, and the City Fathers had their exchange at a local hostelry called the Spotted Dog, still flourishing, especially on football afternoons; probably the building was chosen because many merchants resided in the vicinity. The entries of burials in the parish registers show a fair proportion of deaths from plague. Small-pox, too, is no respecter of

localities or of unvaccinated persons, and in our parish church is a fine monument recording the deaths in 1709 of Amherst Buckeridge, aged 28, and of his sister Eleonore. The inscription states:

"Amherst and Eleonore lived to be remarkable for their great dutifulness to their parents, for their most affectionate kindness for one another, and for their being inoffensive and obliging to everybody. These both died of Small-pox in 15 days' time, one after the other, and whether the grief of Eleonore for the loss of her brother or the small-pox contributed most to her death is uncertain."

Sir Thomas Browne informs us that "some think there were few consumptives in the old world when men lived much upon milk and that the ancient inhabitants of this island were less troubled with coughs when they went naked and slept in caves and woods than men now in chambers and feather beds." Perhaps that is why Richard Mead, two centuries ago, adopted the open-air treatment by sending his consumptive patients to live on Plaistow marshes. At present we send our consumptives to live somewhere else, not because the marshes were unsuitable, but owing to their disappearance, for our present temporary sanatorium is erected in a district of a similar character.

Civilization and communal comfort have advanced apace since Edwin Chadwick, Southwood Smith, John Simon, and their associates forced on public attention the dangers arising from the grosser examples of insanitation, accompanied by annual death rates of 30 or more per 1,000 of the population in urban areas—impure water, decaying hovels, foul streets, want of sewage disposal—all of which reduced to a common denominator meant filth, and we are enjoying the benefit of the fulfilment of their prophetic vision.

Each succeeding age rests upon the shoulders of its predecessor, and we are able to recognize a series of sanitary strata in the life of the nation, as the archaeologists point to layers of towns on the site of Troy—periods of time remarkable for various developments in the direction of public health amenity. Individual sanitarians, specializing on one or more factors of a harmful character, have so focused the interest of their fellows upon their own pet hobby as to secure legislation affecting groups of diseases or classes of the community, with the result that one period stands out as an apostolic age firm in the faith of vaccination against small-pox, another period as pioneer in the isolation of infectious diseases, a third fascinated by the need for factory legislation, and a fourth devoted to the eradication of tuberculosis. The fact that earlier prophecies with regard to the disappearance of tuberculosis still await fulfilment—owing, partly to the war and partly to exuberant optimism—need not damp our ardour, especially since Professor Dreyer's research into defatted antigens; nor need we cease our duty to secure proselytes because a later generation has lost some of its faith in vaccination. Rather let us rejoice that, acting on the advice of Shakespeare, "Wise men ne'er sit and wail their woes, but presently prevent the ways of wail," the pamphlet on *Small-pox and Vaccination* issued by the British Medical Association is evidence that we intend to keep the flag flying.

The increasing knowledge of the causes of disease, the extension of bacteriological investigation, and the romance attending the part played by insects in the conveyance of maladies in tropical and temperate climes, have led the present generation one stage higher by the recognition that all medicine is ultimately preventive and that the claim of the community to protection from sickness overrides the claim of the individual to personal liberty, with the necessary corollary that mass sanitation and group hygiene must be supplemented by organized inspection and treatment of their several units—a policy finding a partial practical consummation in the joint action of central and local authorities in connexion with tuberculosis, venereal diseases, and schemes for maternity and child welfare, and the medical treatment of school children.

Sir George Newman has championed the modern policy with no uncertain voice in his public statements, and with forceful language in his illuminating reports, and few will cavil at his recent insistence upon the essential need for levelling up the individual medical practitioner, and, I humbly admit, especially some individual medical officers:

of health, in order to ensure the healthiest life for each individual man and woman; and even for each foetus to be given an equality of opportunity—so far as that is possible.

So far I have dealt with general principles, but what are the particular amenities of my own district? Like the generality of mundane conditions they are a mixture of good and bad, sunshine and shadow, homely joys, and destiny obscure. Our comparative youth gives us freedom to some extent from some of the worst evils of slumdom; but our rapid growth during the early building boom, when many houses may be said to have been stuck in the mud, has accentuated the universal difficulties of dealing with the present housing problem. The limitation of most of our dwellings to two stories affords the lion's share of sunlight, but this advantage is discounted by the incense which we and our neighbours offer up to the heavens in the form of black smoke; as the greater part of the area is below Trinity high-water mark it may well be supposed that our respiratory functions are subjected to and affected by a denser atmosphere than pertains in more elevated districts, though doubtless rigid research would be required to demonstrate deleterious effects.

Our chief characteristic, however, remains that we are one of the largest and possibly poorest of industrial towns which, taken as a group, compare very unfavourably in respect of their mortality with the country as a whole or with other groups of towns, and *prima facie* West Ham should exhibit an exceptionally heavy death rate. But such is not the case. I will not weary you with statistics—they are recorded by the Registrar-General—but merely make the assertion. The administrative county of London, our immediate neighbour and rich relation, is acknowledged to be one of the healthiest cities in the world, and was rightly claimed by my predecessor to be the triumph of medicine; but while allowing London to be *facile princeps* I claim that West Ham is *proxime accessit*. For a long series of years the annual death rate of the borough has compared not unfavourably with that of the administrative county; the few exceptions have been not more than one or two units per 1,000 of the population, and in some instances merely a decimal point higher. Incidentally you may be assured that the attention of the borough council has been directed to those rare occasions when the death rate was below that of Brighton. Similarly with regard to the deaths among infants, in respect of which a heavy death roll is generally exacted from industrial towns, the decline in infant mortality which has been a distinguishing feature throughout the country during recent years has been equally marked in West Ham, where it has sunk to a figure which at the beginning of the century would have been considered phenomenal.

Without doubt the practical application of the increasing knowledge supplied by scientific workers towards combating all forms of sickness, and especially what Osler called the four killing diseases, has operated as one factor in reducing the death rate by the postponement of death; but just as the four elements—earth, air, fire (in the form of sunshine), and water—are still as potent factors in the economy of Nature as in the days of Hippocrates, so are there still several widely diffused deleterious influences which tend to communal shipwreck and to which it has been my object to direct your attention, as they are not only germane to my subject but appear to offer some answer to my proposition.

Since I prepared these notes Sir Arthur Newsholme, in an address on things that matter in public health, has insisted again upon the direful effects of these influences, and urged that to reach the goal of civic salvation we must sweep away the obstructions of poverty, intemperance, ignorance, and vice. In a few words let me try to show that the various authorities in West Ham are and have been working on these lines according to their ability.

With regard to vice in general, while willing to admit that we are no better than we ought to be in Stratford, we boldly maintain that we are not so bad as some of our neighbours. As for the specific vice of venereal disease we have not only organized, in association with the National Council for Combating Venereal Diseases, special

propaganda campaigns, but before the appointment of Lord Trevellyn's committee the county borough council passed a resolution in favour of allowing pharmaceutical chemists to sell drugs for self-disinfection. That a legal decision prevented the chemists from adopting the decision does not detract from the good intention of the council, which, judging from the said committee's report, was merely a little premature.

Ignorance implies want of either general or special education, both of which are only of social value if they beneficially influence conduct. West Ham has to educate not only the children of its own workers, but also those of many of the workers in London, and is notoriously one of the most necessitous areas in the matter of levying an education rate. During the year 1920-21, while the cost per child for elementary education in 82 county boroughs averaged £213, the cost per child in West Ham amounted to £282, which amount was only exceeded by Bradford and Halifax. I am not aware that any complaint has been lodged that we are extravagant, and may therefore place my town among the wranglers in any list of education authorities claiming to be stalwart fighters of ignorance. The introduction of hygiene into the syllabus of the schools has greatly increased the power of the teachers to aid social amelioration, while with regard to conduct one must not forget the devoted bodies of religious and social workers, the value of whose services resemble the silent forces of Nature—frequently unobserved but none the less incalculable.

There is no need in an assembly such as this to stress the evils of intemperance, nor do I wish to discuss the question of total abstinence. Suffice it to say that while some of us may not be prepared to accompany our abstaining colleagues all the way into the arid confines of prohibition, we may all agree that if the means to do ill deeds make ill deeds done the reasonable reduction of facilities for alcoholic abuse will diminish its evil effects, and in this respect our industrial town is somewhat exceptional. In 1887, when the administration of the licensing laws was transferred to the justices, the population was 186,000; in 1922 it was 300,905. In 1887 the number of licences was 366, in 1922 it was 295; so that while the population increased by 114,905 the licences decreased by 71. Again, last year (1922), in the fifteen largest county boroughs in England the average population to each on-licence was 604; in West Ham the average population was 1,583, or two and a half times as great. The convictions for drunk and disorderly conduct sank from 2,261 in 1911 to 602 in 1921, and he would be a particularly uninformed or prejudiced medical practitioner who would deny even without examining the returns that during the same period the Pale horse of the Apocalypse met a diminishing number of sufferers from alcoholic diseases to pass behind him to Hades.

The poor we have always with us, and in a factory and dock district even in flourishing times casual labour and poverty go hand in hand. Boswell records a dictum of Dr. Johnson thus:

"A decent provision for the poor is the true test of civilization. Gentlemen of education were pretty much the same in all countries; the condition of the lower orders, the poor especially, was the true mark of national discrimination."

Now to test the discrimination of our local board of guardians in respect of outdoor (that is, domiciliary) relief it may be proper to deal with a normal period rather than with a time of exceptional distress, as exists at present from super-unemployment, in which an average weekly cheque of £6,000 for relief has on occasion risen to £22,000. Taking, therefore, the last normal year—that ending March 31st, 1920—the average weekly cost of domiciliary relief per person in receipt of relief was nearly 5s. 7d. for England and Wales, as compared with 6s. 2d. in West Ham. Sixpence a week may appear a trivial sum, but to a widow with three or four dependent children the 2s. or 2s. 6d. weekly it means to her represents an appreciable amount of her total income available for the sustenance of her self and family. To-day in such a case the scale of relief has risen to 5s. weekly for each child and 10s. or 15s. for the mother, with a rent allowance according to circumstances. This may,

appear to err on the liberal side, but the guardians, rightly or wrongly, hold the view that relief should be adequate to the needs of the applicant, and particularly in the case of children, who, well fed rather than half-starved, are much less likely later on to fall victims to sickness and be thrown again on local rates. This surely is an enlightened policy which is followed by the borough council in supplying dried milk free under a liberal wage scale to nursing mothers and young children, as well as by generous provision of convalescent treatment for ailing youth. Carping critics allege that relief schemes foster indifference and mendacity. It may be so in isolated cases, and occasionally one meets with what at first sight appears to justify the criticism. For instance, my chief clerk, crossing the hall corridor, met a little vulgar boy. "Well, my little man, what do you want?" said he. "Please, sir, mother says will you put on a piece of paper what's given away?" His mother's request was not granted, but I fancy assistance followed investigation, and those who practically deal with relief know that the black sheep in every flock are few.

The Autocrat of the Breakfast Table said that no fresh truth ever got into a book, and I have merely been telling you what you know. With much you must agree; from some you may differ—a happy result if it lead to a stimulating discussion, for the man who proudly boasted that he had not had a disagreement with his wife for twenty-five years was promptly told by a sensible woman present that he had led a milk and water existence. In any case, whether I be charged with endeavouring to kill the slain or with setting up West Ham in rivalry with Epidaurus and Cos, I care not; my good intention (not a paving stone, I trust, in this case) has been, in legal phraseology, to obtain a writ certiorari that while it is given to the few to achieve greatness and associate their names with some definite hygienic advance, each one of us, whether medical or lay, official, bourgeois, or representative (if we only have power to live up to our ideal), by lending our aid to wisely directed efforts to eradicate the social evils I have referred to, can definitely improve the public health of the community among whom we dwell and help on the world in its slow but sure journey to ultimate goodness.

In the stirring language of a recent writer to the *Times*, "The ideal is the only real and lasting fact of life, and a man's worth is conditioned by the effort he makes to attain it. He who has given up belief in the certitude of our manhood's perfection must sink back to the indignities of the man with the muck-rake, with eyes bent to earth, forfeiting the true wealth of reality for the glitter of things which leave their possessors in final beggary."

## THE TREATMENT OF TUBERCULOUS DISEASES:

### THE EFFICACY OF SODIUM MORRHUATE INJECTIONS COMPARED WITH OTHER TREATMENTS.

BY

P. W. R. BOELKE, M.B., CH.M. SYDNEY,

HONORARY CONSULTING PHYSICIAN, ANTITUBERCULOSIS DISPENSARY, SYDNEY, N.S.W.

Of all the treatments used for the arrest or cure of tuberculous diseases, apart from or in conjunction with sanatorium treatment, that by means of injections of tuberculin or other chemical preparations has probably been most widely and often most successfully employed. Having had a fairly large experience, extending over nearly twenty years, of these methods, and finding that as time went on I was able steadily to improve upon my procedure, is my excuse for writing this paper.

#### TUBERCULIN.

Many will remember the time when, in 1890, Professor Robert Koch, somewhat against his own wish and before he had completed all his investigations and experiments, was forced by the Government to publish the outline of his new treatment by injections of a "lymph" which he called tuberculin, and which is still known and used under the name of O.T. or old tuberculin.

I have before me a pamphlet, published by the late Professor Anderson Stuart of the Sydney University in

1901, entitled *A Report to the Governments of New South Wales, South Australia, and New Zealand on the Koch Method of Treating Tuberculosis*. The report is interesting but disappointing as regards some of the results. We thought that at last a remedy had been found to exterminate this dread disease. People afflicted with it flocked to Germany from all parts of the world, full of hope, a few to return with their disease arrested, many never to return at all. A treatment which with all its failures could in some cases bring about such startling recoveries was so remarkable that it would have been surprising if it had been altogether shelved. Far from it. It is the foundation stone on which the whole structure of our modern tuberculin treatments has been built.

Some of the first books published on this subject by Camac Wilkinson (1903), Bandelier and Roepke (1911), Riviere and Morland (1912), and others, were all based on Koch's original discoveries. All these authors recommended treatment by Koch's method in a more or less modified form, by subcutaneous injections of various tuberculins in gradually increasing doses at intervals regulated by the resulting reactions (see Appendix A). Of patients treated by me by this method from 1905 onwards there are still a good many alive and well. In contrast to the milder treatment recommended by Sahli I shall call this Koch's treatment.

A few histories of patients with rather advanced disease will suffice.

*Case 1.*—1905. Mrs. G., aged 30 years, weight 41 kg.; ill five years; pronounced tuberculous family history. Both apices affected. Right lung, first stage (Turban's); left lung, second stage; frequent haemorrhages and severe asthma. Sputum contained tubercle bacilli (Gaffky X). Disease arrested after two courses of tuberculin injections. Relapses in 1909 and 1920 easily remedied, the first by tuberculin, the last by sodium morrhuate injections. Weight 79 kg. All this time this patient lived in Sydney, which, on account of its warm and moist north-east winds in summer, is rather inimical to patients suffering from tuberculosis. Practically all the other patients whose history is given were treated under the same climatic conditions.

*Case 2.*—1909. Bro. J. M. Left apex, third stage. Tubercle bacilli in sputum (Gaffky X). Treatments with O.T., P.T.O., and P.T. Quite well to-day and sputum free from tubercle bacilli.

*Case 3.*—1909. Mr. L. L., aged 23 years. Urine contains pus and tubercle bacilli. Diagnosis: Tuberculosis of right kidney. One course of treatment with P.T.O., P.T., and T.B.E. injections. Apparently well. Urine quite clear. Relapse 1914. Treated with P.T.O. and P.T. injections. Quite well at present date. Looks picture of health.

*Case 4.*—Mrs. L. L., wife of last patient, was treated in 1910 for tuberculosis pulmonalis. Has had no recurrence since.

*Case 5.*—October, 1909. Mr. J. H., aged 36 years, weight 63.5 kg. Right apex, second stage. O.T. test positive. Ill twelve months. Diagnosis: Tuberculosis pulmonalis. Six months' treatment with T.B.E. and P.T. Well in May, 1910. Weight 73.5 kg. February, 1911, O.T. test negative. Quite well to-day.

*Case 6.*—February, 1912. Mrs. J. H., wife of previous patient. Aged 25 years; weight 52 kg. Right apex, second stage. O.T. test positive. Ill two months. Diagnosis: Tuberculosis pulmonalis. Eight months' treatment with T.B.E. Weight 53 kg. Well to-day.

*Case 7.*—February, 1912. A. H., daughter of the two previous patients, aged 10 years; weight 29 kg. Right apex, first stage. Von Pirquet test strongly positive. Ill six months. Three months' treatment with T.B.E. Well; weight 32 kg. August, 1915: O.T. test negative; weight 52.5 kg. Strong and well to-day.

*Case 8.*—February, 1916. Mr. J. J. S., aged 32 years, weight 57 kg. Right apex, third stage; left apex, first to second stage. Sputum contained tubercle bacilli (Gaffky X). Sent out from England as incurable. Seemed almost hopeless case. Diagnosis: Tuberculosis pulmonalis. After twelve months' treatment with P.T.O. and P.T. quite well; weight 62 kg. Has just returned from a trip to England well.

I could quote many other histories of patients treated many years ago who are still in good health. All I want to show is that by means of Koch's treatment it is possible to bring about more or less lasting arrest of advanced tuberculous disease. Still, in spite of all these successful results I was never quite satisfied, as in some cases, however small in number, Koch's treatment seemed to fail. Some patients did not improve at all, while others after an initial improvement seemed to relapse. Besides, it did not seem a suitable treatment for ambulatory cases, as patients sometimes during a severe reaction had to lay up for a day or two. On the whole patients afflicted with tuberculosis pulmonalis in all stages seemed to do better than so-called "surgical" cases—a term which I only use because up till

practise, the Board is of opinion that the question of charging midwives an annual fee is one which requires very careful consideration, as in practice it might produce many complications and difficulties.

## Scotland.

### PUBLIC HEALTH AUTHORITIES.

A WHITE PAPER has been issued by the Scottish Board of Health containing two reports by its consultative councils on a reformed local authority for health and public assistance. The first report deals with local health administration and general health questions; the second with the application of similar principles to special conditions of the Highlands and Islands. The reports deal with the local administration of the health and public assistance services by county councils, district committees, town councils, parish councils, education authorities, insurance committees, and other local authorities; and contain recommendations which affect the status and constitution of these authorities, with the object of co-ordinating the local administration of health and public assistance. The price of the White Paper is 1s., and it can be obtained from the Stationery Office (Edinburgh, 120, George Street). We propose to refer to these reports more at length in an early issue.

### PUBLIC HEALTH OF EDINBURGH.

The Medical Officer of Health for Edinburgh, Dr. William Robertson, in presenting the annual report of the Public Health Department for 1922, observes that in the past local authorities have performed their full share of treatment. In the possession of splendidly equipped institutions ready to cope with epidemics and the provision of admirable places for dealing with tuberculosis in all its forms, there is a suggestion that local authorities may have tended to step beyond their sphere. The report urges that they should now concentrate upon methods and means that will reduce the demands upon these institutions; much that is spent upon institutional treatment could be saved if the breeding places of disease were removed. Tangible reductions in the cost of sanatorium treatment and in child welfare schemes could be confidently expected as soon as it was possible to offer improved housing facilities for those most in need of better habitations. Houses could neither be demolished nor closed on a wholesale scale until there was better and more attractive accommodation to offer to the dispossessed. The search for a way to reduction of infantile mortality directed attention to better housing accommodation and improved social habits.

The total number of deaths registered in Edinburgh during 1922 was 7,012, in a population estimated for the middle of the year at 423,155. This gave a corrected death rate of 15.2 per 1,000, as compared with a rate of 14.4 in 1921. The increase might be attributed to an outbreak of influenza in the early part of 1922. Nevertheless, Edinburgh occupied a favourable position as compared with other large centres of population in Scotland; of the larger burghs only two—Clydebank, and Motherwell and Wishaw—showed lower death rates than Edinburgh. In the various wards of the Edinburgh area the greater death rates were found in the more crowded parts; thus St. Giles Ward was highest with a death rate of 19.8 per 1,000. The infantile mortality rate was also highest in this ward, being 141 per 1,000 births as compared with 91 per 1,000 for the city generally. Suburban wards showed much lower figures—namely, Colinton a general death rate of 8.7 and infantile rate of 20, Liberton rates of 11.2 and 76 respectively, and Corstorphine 12.6 and 23 respectively. As showing the severity and suddenness of the influenza epidemic, the following figures are quoted in the week ending January 14th: the deaths from influenza numbered 15 and the death rate from all causes was 18.7; by January 21st the figures were 71 and 34.3 respectively; by January 28th 118 and 45.3 respectively; by February 4th, 99 and 39.7; afterwards they fell off till on March 4th they were 8 and 17.0 respectively.

The statistics of tuberculosis and cancer are of considerable interest. The deaths from tuberculous disease numbered 532, equal to a mortality rate of 1.26 per 1,000 of population. The death rate for respiratory tuberculosis was 0.9 per 1,000, the same as recorded for the year 1921, and the lowest recorded for this city. This would appear to indicate that the disease is gradually yielding to the efforts which are being made to

combat it. On the other hand, the number of deaths from cancer, in all 657 (giving a death rate of 1.5 per 1,000 of population, or nearly one death in every ten deaths), showed an increase of 32 over the previous year. As regards the age of death, 61 were persons under 45 years, 313 were between 45 and 65 years, and 283 were over 65 years.

The total number of notifications of infectious diseases received by the department during the year was 4,888 as compared with 5,952 in 1921. This large fall is in the main to be explained by a reduction of 461 notifications of scarlet fever, and by the fact that chicken-pox ceased to be notifiable in September, 1921, while for nine months in 1921 there had been 505 intimations of this disease. No cases of small-pox were notified during the year. Enteric fever continued to be infrequent; only 16 cases were reported, of which three occurred in one family; there were only four deaths from this disease, of which 2 unfortunately occurred in hospital nurses. The notifications of diphtheria numbered 800 as compared with 991 in 1921, the case rate being 189 per 100,000 of population as against a case rate of 236 per 100,000 for 1921. The mortality from diphtheria was 7.1 per cent. of the cases notified, and it is interesting that this percentage has been lower only on four occasions since the year 1880. The cases of scarlet fever treated in hospital were also of a mild variety.

With regard to venereal diseases, the work has been carried out in association with the Royal Infirmary, the Edinburgh Hospital for Women and Children, and the Royal Maternity Hospital, and out-patient treatment for females had been arranged at several dispensaries. The number of new cases treated in the year was 3,250, and the total attendances numbered 95,383. This shows a slight diminution (159) as compared with the number of new cases in 1921, but a considerable rise in the number of visits.

### RESEARCH DEFENCE SOCIETY MEETING.

THE Edinburgh Branch of the Research Defence Society held a meeting on July 2nd in the Physiology Department of the University, Sir Edward Sharpey Schafer occupying the chair. Office-bearers and council for the ensuing year were elected, and the report by the honorary treasurer, showed a balance of £43 3s. 6d., from which it was resolved to forward a contribution of £30 to the funds of the parent society in London. A lecture was afterwards delivered by Dr. John Comrie, lecturer on the History of Medicine in Edinburgh University, dealing with "Edward Jenner and Vaccination." The lecturer sketched the early life of Jenner, dealing especially with his friendship for John Hunter and the long-continued correspondence between the two men, Jenner's early reputation as an expert naturalist, his researches upon the habits of the cuckoo, which had been confirmed in the last few years by cinema-photography, and his great popularity as a practitioner. Jenner's labouring efforts to elucidate the problems of cow-pox and small-pox were next dealt with, and finally a number of slides were shown illustrating the great decrease that had taken place in the incidence and mortality of small-pox in association with vaccination and revaccination.

### VISIT OF DR. W. MAYO TO EDINBURGH.

A lecture was delivered last week to the students attending the class of clinical surgery by Dr. William Mayo, Rochester, U.S.A. The address was delivered in the M'Ewan Hall of Edinburgh University, the chair being taken by Sir Harold Stiles. The subject was "Some of the allied sciences in relation to surgery," and a considerable part of it was taken up with a discussion of physics in relation to surgery. The lecturer believed that the recent great advance in medicine came by way of biophysics and biochemistry, between which the borderline had disappeared. A hearty vote of thanks was proposed to the lecturer by Professor Lorrain Smith, dean of the Faculty of Medicine.

## Ireland.

### FREE STATE INTERNMENT CAMPS.

THE report of the International Committee of the Red Cross was placed before a recent sitting of the Dail by General R. Mulcahy, Minister of Defence. In the course of the report it was stated that: "As a result of the numerous representations made to it on the subject of the

of prisoners in Ireland, the International Committee of the Red Cross appointed Mr. Schöner and Dr. Dublin to obtain information from the Irish Government as to the position of the prisoners.

With reference to the conditions at Newbridge the following observations are contained in the report:

Patients—30 men in the infirmary. The former recreation hall has been converted into an infirmary. A special department is set apart for the treatment of those suffering from the itch. The medical staff consists of two army doctors and several army nurses. There is a daily medical visit. No epidemics. Two distinct rooms are in working order. Organization and complaints—the same as at Kilmainham. Correspondence—reception and dispatch—opened under supervision. Patients are distributed regularly but must be left each week.

## Correspondence.

### EARLIER NOTIFICATION OF TUBERCULOSIS.

Sir,—The letter of the Deputy Clerk of the London County Council (published in the British Medical Journal last week, p. 43) is well timed. There is no doubt as to the importance of the issue he has raised. The whole subject of notification of tuberculosis merits consideration on the part of administrative authorities, central and local, no less than on the part of medical practitioners, collectively and individually. Because of that the subject has been selected for discussion at the Annual Conference of the National Association for the Prevention of Tuberculosis to be held at Birmingham this week. It may be expected that many points of interest will emerge and conclusions of practical moment be arrived at.

I would not wish to forestall the discussion. But, as the meeting will be over before this letter can appear in print, you will perhaps permit me to draw attention to the proceedings of the meeting which will in due course be reported. Meanwhile, as one who comes much in contact both with doctors and with administrators concerned with the matter, and likewise with students in training for the profession, I would voice the view that failures in respect of notification in part occur *per incuriam*. The hard-working doctor, not trained in business habits, is a little prone to slackness in respect of what may appear to him as a formality. To this may be added that the attention of many practitioners, especially in the past, has not been focussed forcibly drawn to the point. Apart from the more urgent motives which is present to his mind in connexion with acute fevers.

In some parts of the country the evident benefit accruing to the patient from notification—in the way of facilities for treatment and prevention and economic assistance—is so slight as to offer little stimulus to the medical attendant. Indeed, to some extra-conscientious doctors it may seem that the disadvantages possibly accruing to the patient from notification, especially in some areas, outweigh the advantages, while, perhaps, some more timid individuals may be fearful of the results attaching to a reputation for over-zeal in obeying the statutory demand. It may be that in this respect an easy-going, casual attendant is even preferred to the other.

However produced, the neglect to notify, and particularly the failure to notify at an early stage, is finally fraught with disadvantage to all concerned, and plays a considerable part in neutralizing the efforts of preventive medicine. A good deal, it seems to me, might be done by the health authority, local and central, to increase the doctor's interest in the procedure. A telling statement from headquarters, or a sensible conversation, would in this regard have the opposite result.

Emphasis should certainly be laid on the facilities for diagnosis and for treatment which exist widely throughout the country, and on the value of notification in the direction of interesting and improving such when they are inadequate. From the published health reports it is evident that quite a number of medical officers of health have adopted measures likely to be helpful within their area. A comparison of different areas in respect of the

by the delegates:

The following are extracts from the report

I number of prisoners and internecines is about 11,500 50 women. Our delegate visited the principal camps, a total of 7,563 prisoners. The treatment of these s devoid of all hostile spirit, and the general principles of the 10th International Conference of the Red Cross requested by the International Committee of the Government refuses the status of "prisoners" to the prisoners, but in reality treats them as such. At no time did he find a wounded or sick person left in the camps. On the contrary, he found every medical officer organized medical service.

On this subject appear to him unimpaired. The serious actual-ize was not able to visit the prison at Kilmainham, women are detained, but he has no reason to believe that these prisoners had been on hunger strike since the first arrest to obtain their release or immediate trial, a protest against the prison regime. This fact is very far from written statements. The delegate did not consider that his intervention, unimpaired, would only en-lead his refusal to touch with these prisoners, writing his refusal to these prisoners was released. One of the old North Dublin Union are in the course of the reception of those detained in Kilmainham, illings, with the surrounding garden, will fulfil all hygienic conditions.

Instructions given by the International Committee of the to the delegate exclude certain representations and notes bearing on individual complaints. It is a fact that these hospitals has not been interfered with. grounds for the complaints of overcrowding in Mount-ing of the hospitals is not replaced in case of willful medical care, or treatment, not having been authorized in the prisoners. The men are not obliged to do any work, and are at liberty to walk about the enclosure and I was present at a football match.

For inspection to the camp made a favourable impression of the conditions correspond with the normal treatment of men in the infirmary, 25 men in the surgical hospital. 6 wooden barracks used as an infirmary; these buildings, condition and well heated. The sanitary staff is com- three medical doctors and army nurses. A medical officer, a certain number of men who arrived the health authority, local and central, to increase the doctor's interest in the procedure. A telling statement from headquarters, or a sensible conversation, would in this regard have the opposite result.

Emphasis should certainly be laid on the facilities for diagnosis and for treatment which exist widely throughout the country, and on the value of notification in the direction of interesting and improving such when they are inadequate. From the published health reports it is evident that quite a number of medical officers of health have adopted measures likely to be helpful within their area. A comparison of different areas in respect of the

exhibited charts of fields taken under similar conditions with the same apparatus, and the patients were reliable—that is, the fields were comparable with each other. A normal field was shown for comparison. In all the cases central vision was 6/5 partly, except in the cases of acute and subacute glaucoma, in both of which it was 6/9 partly. The tensions were taken with the Schiotz tonometer, the weight used bringing the pointer between 2 and 4 degrees on the scale, except where the reading with the 5.5 gm. weight was greater than 4 degrees. Once he had taken a field two days before a severe acute glaucoma, and once two days before a subacute attack; in both there had been slight preliminary signs. In the first the limitation was concentric, in the other nearly so; in both there was hardly any enlargement of the blind spot.

**First Group.**—In this group three fields of essentially chronic glaucoma with the same features were shown. In two the 1/1000 fields had contracted within the angle which would have intersected the blind spot. For a concentric limitation to be maintained, it was necessary that the blind spot should not be much enlarged; for if enlargement occurred the field would conform to the ordinary glaucoma field. One case having a tension of 60 mm. was very interesting, for the cup was a tiny, shallow dimple. In an observation made six months later a concentric field was maintained, but the 1/1000 field was just internal to the blind spot, the tension being 55 mm. These cases showed no relationship between the size of the optic cup and the alterations in the field outline. One of them had a fairly large cup (65 per cent.), but this had had no effect upon the blind spot. The last case, with a tension of 32, a full field for 3/1000, and a diminution only in the 1/1000 field could not be considered normal because the other eye had advanced glaucoma with a tension of 100 mm. These three chronic cases formed a series of decreasing tensions, yet not differing greatly in their fields. It might seem that a generalization could be made, and be supported by other cases, that these cases progressed slowly and were very amenable to eserine; but the rapid increase to acute and subacute glaucoma in the two previous cases effectually disposed of this assumption. Nevertheless, he felt that in this type of case the outlook was better than in those showing marked enlargement of the blind spot.

**Second Group.**—In contrast with the above cases, three fields showing functional limitation were shown. The first was shown as a typical concentric field in asthenopia occurring in a case of pulmonary tuberculosis. The remaining three charts, each from a different patient, showed respectively the 1/1000 field outline approaching the blind spot, the latter opening out upwards, and the outline internal to the blind spot. The resemblance of the outline in the middle case to that of an early glaucoma outline was apparent. The tension in this case (19 mm.) was so well within normal limits that there would be little danger of confusing it with glaucoma; but were its tension higher, doubt might easily arise. The tension of 25 mm. in the last case, when compared with cases in the following group of variable tensions, might easily give rise to suspicion; but other circumstances led to there being little doubt as to its functional nature.

Thus a consideration of these two groups showed that (a) the glaucoma field might be concentric and thus resemble the typical functional limitation; (b) the field for 1/1000 in some functional cases resembled that for 1/1000 in some typical glaucoma cases; (c) serious difficulty might arise in distinguishing between these two groups in cases where the tension was near the higher normal limit.

**Third Group.**—The group with tension not high but variable was illustrated by four charts. In one of them (27.44—B) the outline for 3/1000 was full, in the others a little concentrically contracted. The 1/1000 outlines were much more variable, two being fairly typical of glaucoma (A and B), the others rather of the concentric type. The variability of the tension was:

|   | Maximum. | Minimum. | Difference. |
|---|----------|----------|-------------|
| A | 30       | 15       | 15          |
| B | 27       | 13       | 14          |
| C | 28       | 23       | 5           |
| D | 32       | 23       | 9           |

It was obvious that the maxima were near or above the normal limit, the minima below it; most of the cups were above the average size. Consideration of all the signs justified the diagnosis of early glaucoma. It was well known that the tension in the same healthy eye might vary at different times; but he thought that much variation with a persistent alteration in the field justified the conclusion that the intermittently high pressure had produced the alteration in the field. An increased tension which altered vision was glaucoma.

**Fourth Group.**—Only one chart was presented showing a limitation of the 1/1000 probably due to dental sepsis. It was not marked and was accompanied by a slight enlargement of the blind spot. It might be regarded by some as a slight retrobulbar neuritis.

Two cases (B and C) in the third group had *B. coli* in the urine, and showed an improvement in their general health as well as the field when a combined treatment by a vaccine and eserine drops was carried out. In a good proportion of glaucoma cases this bacilluria occurred, and was, he believed, a distinct factor in the causation of glaucoma.

He showed these charts as illustrations of difficulties all had to contend with; he had no royal road out of them. In doubtful border-line cases the use of eserine and a study of the subsequent alterations in the field and tension was the

obvious method to employ, notwithstanding the difficulties in connecting any treatment with subsequent alterations in cases. The suggestion effect of treatment, particularly in neurotic people, was well known; if a field contraction was functional, an improvement after eserine might be due to suggestion. Yet neurotic people might have real ailments; no alteration must be called functional until any possibility of actual lesion had been excluded. There were few more difficult tasks than to detect the earliest onset of a disease in a neurotic patient when an important symptom such as an alteration in the field of vision might be similar in the two conditions.

#### Opener's Reply.

Dr. A. H. H. SINCLAIR, in reply, remarked that the value of the findings depended on the way in which the work had been done, and on the nature of the case. He thought that the method was of the first importance, as was also the proper understanding of the method—of what could, and what could not, be expected from it. The question of fatigue was very important, and in this connexion it was necessary that the examiner should be able to carry through the examination in as short a time as possible, not delaying over doubtful areas but rather giving the patient a short rest and testing them a second time. He agreed that unintentional interruption was bad, and that the test object should be moved freely on the end of a suitable carrier held in the hand. The size of the white or coloured test object should be changed according to the necessity of the case; this was an essential of the quantitative method. He regarded it as important that the patient should understand so far as was reasonably possible what he was desired to do—for example, keep his eye on the fixation point, etc. Intellectual honesty was an absolute essential which should be most carefully and scrupulously practised. The instruments preferred by him were a modified Priestley Smith's perimeter and the screen of Bjerrum. Mr. Neame had stated that he had not used the same size of test object at the different examinations. It was sometimes necessary to alter the size of the test at different examinations, but this should not be done except for good and necessary reasons, which were no doubt present in Mr. Neame's case. The scotoma of pituitary tumour did vary from time to time. In reply to Mr. Bishop Harman he agreed that in the employment of Bjerrum's method, or the quantitative principle, there were difficulties incidental to the method and also to the type of relative defect which this method was intended to investigate. So long as they were concerned with the diagnostic value of relative defects in the field of vision, which were recognized as being of practical clinical importance, difficulties of several kinds could not be avoided. He thought Bjerrum's method had already proved of great clinical value. With regard to the movement of the test object, it should be moved from the area of reduced to the area of best preserved vision and also in the other direction, and the intermediate position be taken as the margin of the scotoma. A colour test was of great practical value as colour, apart from the degree of illumination. In reply to Major Wright, he stated that in the early diagnosis of glaucoma absolute defects connected with the blind spot as demonstrated by Seidel were usually preceded by a wider relative failure, but this sign did occur. It was good practice to relate a scotoma to the size of the test object with which its presence had been demonstrated. This was better than using the terms "absolute" and "relative." In reply to Sir John Parsons, he agreed that conditions under which examinations of the field of vision were made were not sufficiently uniform, yet valuable facts could be demonstrated for clinical purposes under considerable range of variation in the conditions. The amblyopic zone round the blind spot was, as Sir John Parsons said, normally present, and care must be taken not to confuse the normal extensions of this zone with abnormal change. The question of the intensity of stimulus from a scientific point of view had not been under consideration; his own approach had been entirely from a clinical point of view. Mr. Pickard had shown examples of fields in glaucoma in which concentric contraction was the principal feature. He himself had seen such, but using the quantitative method they were, in Dr. Sinclair's experience, very rare.

### MEDICAL, SURGICAL, OBSTETRICAL.

#### ERYTHROMELALGIA TREATED WITH COLLOIDAL CALCIUM.

IN view of Dr. McCormick Mitchell's account<sup>1</sup> of the results of the treatment of urticaria with colloidal manganese, I should like to record the following case.

I have had under my care for the last three years a patient presenting that rare condition first described by Weir Mitchell under the term "erythromelalgia." A woman, 55 years of age, suffers, particularly during the warmer months of the year, from great pain, redness, and swelling of the feet. The swelling is much aggravated by the fact that her household includes five wage-earners, and she is "cumbered about much serving." By the end of the day the swelling of the feet is extreme, although pitting is but slight, and the congestion is almost cyanotic. Treatment of these cases is disappointing, and I had achieved no success whatever throughout two summers when this year I decided to try the effect of colloidal calcium. Beginning with 0.25 c.cm. of "collosol" calcium subcutaneously, I gave at weekly intervals six other injections each of 0.5 c.cm. It was difficult at first to estimate the degree of improvement as the patient's symptoms had previously varied a good deal from day to day, but any doubt as to the benefit of the treatment was dispelled after the fourth injection, which coincided with the advent of some extremely hot weather at the beginning of July. Ordinarily the patient would have been moving about her house with great difficulty, the pain in the feet being of an intense burning character, and the swelling over the dorsum bulging enormously. Instead of that she was able to walk with comfort in a pair of slippers of normal size and shape. This improvement has been maintained up till now.

I do not say that the condition is cured, but that the treatment has been of the greatest value cannot be denied. Further treatment just now would be inconclusive as there is in her case a spontaneous alleviation of the symptoms as the weather cools. In the event of a recurrence next year I would be inclined to repeat the course with the dosage doubled. I had never tried calcium in the form of lactate in this patient, but in view of the fact that that salt is found to be of benefit in certain cases of Raynaud's disease and of angio-neurotic oedema (as it is in urticaria) it would be of interest to know the effect of a colloidal preparation in these conditions.

The etiology and pathology of the angio-neuroses are shrouded in obscurity, and it may be that time will elapse before they emerge from the slough of our ignorance, but perhaps it is of more than passing interest to note that on one occasion shortly after the patient came under my care I gave her a mixture of potassium iodide. After a 15-grain dose she passed a very restless night and I was sent for the following morning to find her with the shoulders, buttocks, and front of the thighs covered with large wheals, some of them already bullous and containing a clear exudate. The mucous membrane of the mouth was much swollen, and she had had a sensation of choking which was passing off when I saw her. I stopped the iodide, and have never given it since, but would be tempted to risk investigating this idiosyncrasy again after a further course of calcium.

Dundee.

JAMES M. STALKER, M.B., Ch.B.St. And.

#### ALCOHOLIC CIRRHOSIS.

THE two following cases of cirrhosis of the liver appear to me to be of sufficient interest to place on record:

*Case 1.*—Male, aged 45, a beer drinker; atrophic form. When first seen he showed ascites and oedema of legs and scrotum. He was tapped fifteen times at intervals of ten to fourteen days; one and a half to two gallons of straw-coloured fluid were removed at each tapping. At that time the patient abstained from beer and indulged only in small tots of whisky. After the fifteenth tapping the ascites and oedema did not return for eighteen months. He then returned to his beer, and almost immediately the same train of symptoms reappeared. A further series of thirteen similar tapplings completed this attack, the beer being stopped meantime. He remained free for two years, then his wife's sudden death led him to begin drinking beer heavily again, and the same train of symptoms recurred. As I was away on active service he refused to see a doctor. He was therefore not tapped again, gradually sank, and died. In all, from the commencement of the first attack, this patient lived five years.

*Case 2.*—Female, aged 53, a spirit drinker; hypertrophic type. When first seen she had ascites but no oedema of the legs. She was tapped twelve times at intervals of three to five weeks; at each tapping one to one and a half gallons of straw-coloured fluid were removed. After the twelfth tapping the fluid did not re-

appear. The patient did not altogether give up alcohol, but diminished the quantity. She is still alive and enjoys fair health. The period from the commencement of illness to the present time is five and a half years.

In neither of these cases did the site of puncture give any trouble, although on several occasions there was rather severe haemorrhage owing to puncture of superficial vessels, but pressure easily controlled this. Medicinal treatment was of no avail: potassium iodide and blue pill were tried but could not be tolerated.

Sanderstead.

JOHN FINNEGAN, M.C., M.D.

## Reports of Societies.

### EDINBURGH MEDICO-CHIRURGICAL SOCIETY.

A CLINICAL meeting of the Edinburgh Medico-Chirurgical Society was held in the Royal Infirmary on November 21st, with Sir DAVID WALLACE, President, in the chair. The following clinical cases were shown.

Mr. J. M. GRAHAM showed a case of haemophilia in a boy aged 8, illustrating the value of blood transfusion as a means of arresting the haemorrhage.

There was no family history of haemophilia and this condition was not suspected till circumcision was performed when he was 15 months old, and bleeding persisted for several days. Since the age of 2 he had seldom been without some haemophilic sign or symptom. In August, 1923, he cut his foot and the usual methods of attempting to arrest the bleeding completely failed. Signs of collapse developed, a donor was obtained and 500 c.cm. of citrated blood was transfused. During the operation the wound was exposed and clotting took place after 200 c.cm. of blood had been transfused. He made an excellent recovery, but haemophilic symptoms had recurred since then.

It was therefore obvious that although transfusion of blood might have an excellent temporary effect it would not prevent recurrences at a later date. The suggestion was made that possible donors for haemophilics should have their blood tested before the emergencies arose.

Miss GERTRUDE HERZFELD showed examples of two rare acute abdominal conditions in children.

The first case was that of acute cholecystitis in a girl aged 6½ years. Four days before admission vomiting and acute abdominal symptoms began and persisted; her mother thought she looked a little yellow. Definite resistance was made out in the right hypochondrium and immediate operation was decided on as she had an obvious infection. A right rectus incision was made, and an enormously distended gall bladder appeared, from the fluid of which paratyphoid organisms were isolated. She made an uninterrupted recovery.

The second case was that of a Meckel's diverticulum with perforation in a boy of 3 years. He was admitted to hospital with a two days' history of melaena, but under chloroform no abnormal abdominal swelling could be made out. He was treated medically, and ten days later he developed suddenly an "acute abdomen." Immediate operation revealed a diverticulum 2½ feet from the ileo-caecal valve with a small perforation at its junction to the small intestine. Four inches of ileum was resected and an end-to-end anastomosis performed. Dr. James Dawson cut sections of the ulcer, which showed mucous membrane with acid-secreting cells resembling that of the stomach.

Sir HAROLD STILES showed two cases:

A male, aged 50, who had suffered from tic-douloureux, the symptoms commencing suddenly eight years ago. Attacks at first were preceded by a tingling sensation in the region of the right molar tooth. The condition became gradually more intense and in 1919 a portion of the inferior dental nerve was resected: complete relief resulted for about a year. The pain then recurred, involving the second and third divisions of the nerve and rendering life almost unbearable. Division of the root proximal to the ganglion, the "physiological operation," was carried out, which operation was first performed by Frazier of Philadelphia after physiological experiments made by Spiller. The patient has been free from pain since the operation. There is complete anaesthesia in the distribution of the fifth nerve, but he is able to chew equally well on both sides.

A male, aged 62, who had the anterior half of the tongue excised for epithelioma in April, 1921, six weeks later the glands in the digastric and carotid triangles were removed. These glands under the microscope showed no evidence of malignancy. A few weeks ago, however, hard glands were detected in the lower carotid region and were removed together with the lower part of the sterno-mastoid, a portion of the external jugular vein, and part of the vagus, since they were fixed and adherent.

Mr. J. W. STRUTHERS showed two cases:

A man of 53 years, suffering from osteitis fibrosa in a relatively mild form, who had been admitted to hospital with a compound fracture of the right forearm, the result of an accident. X-ray examination showed the right radius thickened and curved in its

sists of the medical officer of health. In spite of the  
various difficulties, however, there is a gratifying improve-  
ment in the general health throughout the area of British  
administration.

THE VALUE OF MENTAL AND SCHOLASTIC TESTS.

In the course of some investigations among physically  
defective children it was found that not only in scholastic  
tests, but that they were much below the average, but also  
contrary to accepted views, those so-called "mental"  
tests were equally low. Terman says that the lack  
of schooling does not prevent a subject from earning an  
average or superior score by the tests employed, but  
Mr. Burt inclined to the view that "barren is the growth  
of opportunity." In order to ascertain which of  
these pronouncements was the nearer the truth, Mr. Hugh  
Tredwell, one of His Majesty's Inspectors of Schools, made  
an investigation during the course of his official work, and  
a report has been published by the Board of Education,  
dealing with physically defective, canal boat and gipsy  
children, and backward children in ordinary elementary  
schools, but the scope of the paper is better indicated by the  
title, "An inquiry into the effects of schooling on the  
various tests." The tests employed were those of Terman,  
employed in small points to meet local necessities. Among  
children in physically defective schools there was found  
an average "mental" and "educational" ratio. The  
question was whether this was due to social environment,  
lack of schooling, or to the physical defect.  
School condition was ruled out, since the employment of  
parents did not differ materially from that of parents  
of children in the ordinary schools, but the physically  
defective children made only an average percentage attend-  
ance of 48 per cent., as against 88 per cent. for the ordinary  
children. Heart disease, infantile paralysis, and tuber-  
culous troubles were by far the most prevalent physical  
defects, and differences of response were found accordingly.  
Heart cases gave the best response, but  
never attendance was best; infantile paralysis gave the  
worst; cases of hemiplegia gave bad responses even though  
their attendance percentage was high. The conclusions  
were justified that the physical defect in the majority of  
cases had a marked influence in reducing the amount of  
school attendance, that though this reduction of schooling  
also had a corresponding effect on both the "educational"  
and "mental" ratios, and that to a certain  
degree the intelligence tests are tests of school attain-  
ment. The second set of children investigated were canal  
boat children. They are clean and well fed, life on board  
boats is almost patriarchal, morality is good, discipline  
is strict, but the schooling is minimal. It is calculated that  
canal boat child gets something like 4 to 5 per cent.  
attendance as against 88 per cent. attendances of the  
ordinary child. The "intelligence" test response was low,  
there was a decided decrease of "intelligence" with  
increase of age. The conclusion arrived at was that  
without education or schooling children are very much  
undervalued when tested by the "intelligence" tests, and  
nearly to the same extent as when tested by purely  
scholastic tests. Gipsy children live a nomadic life, but  
anliness is equal to that of the agricultural population,  
they have plenty of social intercourse. Their health and  
school attendance is irregular (55 per cent.). The mental  
tests used did not measure native ability apart from  
schooling except in the case of very young children. Mr.  
Tredwell suggests that there is need for a further investiga-  
tion to discover by means of specially devised environ-

Board of Education, Educational Pamphlets, No. 44. Mental and  
scholastic tests among retarded children, physically defective, canal boat  
children, and backward children in ordinary elementary schools.  
H.M. Stationery Office, 1931. 52 Price 1s. 3d. net.

mental tests whether in such children as gipsies and canal  
boat children there has been any further mental develop-  
ment in other directions; he is inclined to think that there  
are such developments amongst gipsies but not in canal  
boat children. When backwardness in children is due to  
natural dullness, schooling does not bring any all-round  
development; although they can accomplish certain  
scholastic tests in matters they have been taught in school,  
they are unable to do equally well in those matters upon  
which they have not been instructed and which require  
some thought. In other words, the more these children  
attend school the greater their scholastic ability but the  
less their "intelligence," at least with children naturally  
dull and attending such classes as those investigated.  
Whether totally different methods of instruction would pro-  
duce similar results is a most interesting problem. The  
general conclusion of the investigation—which is related in  
much detail, so that the methods of working can be tested  
by other observers—is put thus: "It is quite evident that,  
although the mental tests used on undoubtedly test some  
kind of ability or abilities, such abilities are not developed  
without schooling or its equivalent, and as a consequence  
the tests do not evaluate them apart from schooling,  
except perhaps in the case of children under 6 or 7 years  
of age." This is a very direct challenge to the value of the  
tests, and one that will doubtless stimulate much heart-  
searching among school psychologists.

MODE OF ACTION OF DISINFECTANTS.

The fifth report of the British Association Committee on  
Colloid Chemistry, issued recently by the Department of  
Scientific and Industrial Research, deals for the most part  
with industrial problems, but contains one article on colloid  
phenomena in bacteriology which is of considerable medical  
interest. It is by Dr. E. K. Rideal, who makes an  
ingenious attempt to explain the specific disinfectant  
action of drugs in terms of modern physical chemistry.  
Dr. Rideal's explanation of the specific action of drugs and  
toxins was a purely chemical conception; drugs were  
supposed to contain hapdophore groups which possessed  
a specific chemical affinity for special groups in bacteria;  
the usual metaphor used was that of the lock and the key,  
and the action of the drug (the key) depended on it fitting  
the lock (the bacteria). More accurate analysis of the  
mode of action of disinfectants, aided by the recent  
advances in physical chemistry, showed that the action of  
disinfectants depended very largely upon physico-chemical  
forces, and that adsorption in particular played a very  
important part. Langmuir and others have shown that  
organic substances tend to be concentrated in a mono-  
molecular layer on the surface of a watery solution, and  
that the molecules are orientated in a particular manner,  
for example, in the case of a fatty acid the COOH or  
polar group is attracted to the water, whilst the rest of  
the molecule tends to resist immersion in the water and to  
pass into any lipid material. In the case of most organic  
disinfectants this phenomenon of surface adsorption will  
explain how a considerable concentration of disinfectant  
can be produced on the surface of bacteria when they are  
immersed in a very dilute solution. If the organic dis-  
infectant consists of a complex nucleus with various polar  
or reacting groups such as NH<sub>2</sub> or OH, then Dr. Rideal  
argues that this nucleus, which is soluble in lipid, will  
tend to carry the disinfectant into the lipid-containing  
surface membrane of the bacteria, and the reacting groups  
will then react with the protoplasm of the bacteria and  
produce the germicidal action. On this hypothesis the  
germicidal action depends on two properties of the dis-  
infectant—the possession of a lipid soluble nucleus and

distal half with irregular calcification and a cyst-like appearance at the distal end. The right tibia was curved forwards and considerably thickened with irregular calcification, which was also present in the head and upper part of the right humerus. The Wassermann reaction was negative, and he had no symptoms arising out of the bony lesion.

A case of severe haemorrhage following gastro-enterostomy with clamps. The operation was simple, but on return to bed symptoms of severe internal haemorrhage developed and when the abdomen was reopened bleeding vessels were found on the posterior line of suture.

Sir ROBERT PHILIP showed three cases of extensive multiple tuberculous lesions illustrative of two points in treatment: the length of time necessary to get good results, and the importance of employing a suitable antigen (tuberculin) constantly while under treatment. One patient had had tuberculous disease of the tibia with a chronic discharging sinus and much evidence of toxæmia: the local process was now healed and she had put on nearly 2 st. in weight. The second patient was a "mass of sores," who had been treated for twenty months. The sinuses had all healed and she had gained 3 st. in weight. The third patient had twenty-three discharging sinuses with severe toxæmia: she had been under treatment for twenty-six months. The sores with one exception were now healed, and she had gained nearly 2 st. in weight.

Professor LOVELL GULLAND showed two cases:

A case of bronzed diabetes, or haemochromatosis, in a female. The diabetes was not of a severe type, but the point of interest was the distribution of the pigment, which was very definite over the front of the abdomen and thorax, but did not show nearly so much on the exposed parts.

A patient with Addison's disease who was sent to hospital as an undiagnosed gastric case. In the course of the routine examination marked pigmentation of the Addison type was detected on the inside of mouth, cheeks, hard and soft palate, and gums; this had increased since admission, and the blood pressure had become lower. The liver was enlarged and hard, and the question arose whether this was only an incident or whether the condition was one of neoplastic involvement of the suprarenals secondary to the liver. There was no other evidence of tuberculosis.

Dr. R. A. FLEMING showed a case of hemiparesis, astereognosis, and homonymous hemianopia in a man aged 56 whose Wassermann reaction was negative. He suggested that the lesion was one of thrombosis in the right occipital region involving the sensory, and also possibly the motor, part of the posterior half of the internal capsule. The patient had improved considerably under potassium iodide.

Mr. HENRY WADE showed a case illustrating the operative treatment of chronic pleural empyema by a two-, or possibly three-, stage operation.

Stage one is carried out by making a horseshoe flap, exposing three ribs at the most dependent part, and resecting and establishing very free drainage.

Stage two is carried out about three months later; the ends of the horseshoe-shaped incision are extended, and this flap of skin and muscle is dissected up. The chest wall over the cavity is excised. The subscapularis and infraspinatus muscles are detached and the lower portion of the scapula beneath the spine is removed. The separated muscle tissue is used as a graft to fill the upper part of the cavity. The horseshoe flap is replaced.

If a third stage is required it consists of the replacement of the flap.

In all cases operated on by Mr. Wade healing had been rapid and the ultimate result most satisfactory.

Dr. MURRAY LYON showed a case of acute nephritis which failed to react to ordinary medical measures. After three months' medical treatment Sir David Wallace "decorticated" the right kidney, the result being a temporary improvement in the urinary excretion for two weeks. Six weeks later the left kidney was "decorticated" and general improvement occurred, both as regards the urine and the general oedema.

Mr. JOHN FRASER showed a patient with developmental tumour of the hypophyseal stalk, who was admitted to hospital complaining of adiposity, squint, headache, and deterioration of vision. X rays revealed the tumour, which was partly cystic, calcified, and probably epithelial in structure. Some ten similar cases were on record, with successful operative removal in one instance. Extensive decompression of the right side of the skull was carried out with considerable improvement.

Dr. NORMAN CARMICHAEL showed a case of congenital pyloric hypertrophy in a male infant of 2 months, treated successfully by operation; also a cretin boy with characteristic features.

Dr. L. S. P. DAVIDSON exhibited a case of lead poisoning in a man who worked as an oxy-acetylene blower in a ship-breaker's yard, and showed the typical blue line below the few teeth he possessed, weakness of arms, anaemia, and punctate basophilia. The interest of the case lay in the fact that lead poisoning could occur at this work. He had to cut bolts or rivets with intense heat; he showed no symptoms while working in the open, but when working in the "tunnel shaft" symptoms appeared. The rivets were fixed in position with a collar and thread saturated in red lead. The intense heat of the blow-lamp broke up the red lead into fine particles, which he inhaled.

Dr. W. T. RITCHIE showed a woman, aged 58, suffering from chronic mitral incompetence who developed auricular fibrillation. She was treated with *digitalis* and after the signs of cardiac failure *digitalis* sulphate was given. Normal rhythm was restored after 0.8 gram had been given, and it had been maintained for a month with 0.2 gram twice daily. Mr. GORDON BELL showed a case of ulnar paralysis following a supracondylar fracture of the humerus. At an operation performed to relieve the pressure it was found that the nerve still functioned normally, although the muscles of the hand were much wasted.

Mr. PIRIE WATSON showed: (1) Two cases of compound dislocation of the lower end of the ulna associated with fracture of the radius in its lower third. One was caused by a chauffeur "cranking up" his car with the thumb round the starting handle, and the other occurred in a female patient aged 74, who fell heavily when rising from bed in the dark. Both exhibited good functional results following treatment. (2) A transverse fracture of the patella which was sutured with chronic catgut five months ago. A radiogram taken recently, two days after he had slipped on an icy pavement, severely straining his knee, showed the fragments in close apposition and apparently united.

Mr. J. J. M. SHAW showed: (1) A case of loss of one eye with shrinkage and distortion of the socket following fracture of the orbital plate. In nine cases out of ten the socket could be reshaped, but in a few this was not possible. In this particular case the ciliary margins, lacrimal gland, and conjunctiva were removed, the lid edges sutured, and a shade worn. (2) A case of chronic varicose ulcer of twenty-two years' duration where an abdominal pedicle was in the stage of transfer to the leg. At present the lateral end of the pedicle is implanted in the upper third of the thigh. In the next stage the end of the pedicle will be implanted near the ulcer; later the pedicle will be fully opened up and used to cover the whole area of the ulcer.

Mr. J. N. J. HARTLEY showed: (1) A case of cirrhotic aneurysm in the left frontal region, which was first observed in infancy; it attained the size of a walnut and caused annoyance by a bruit which was most marked when the patient was in bed; Krogus's operation, combined with injections of alcohol, yielded good results. (2) A case showing reconstruction by a two-stage operation of a thumb mutilated by a mine explosion; the first operation was designed to preserve tissue, the second to restore function. (3) A case of a compound tuberculous former ganglion which had resisted conservative treatment; complete removal was considered advisable.

## INDUCTION OF LABOUR BY QUININE AND PITUITRIN.

At a meeting of the Edinburgh Obstetrical Society held on Wednesday, December 12th, with the President, Professor B. P. WATSON, in the chair, a communication was read by Dr. F. J. BROWNE on the induction of labour by quinine and pituitrin. The speaker referred to the researches of Oliver, Schafer, Dale, and Blair Bell in connexion with the discovery of quinine and of its effect in producing uterine contractions, and to the investigations of Fries, Haugh and Meyer, Stein and Dover, and Cron, and of B. P. Watson on its employment in the induction of labour. In 1922 Watson had published the results obtained in a series of 195 cases, in 90 per cent. of which labour was successfully induced with no maternal mortality and a foetal death rate of 6 per cent.; none of these deaths could fairly

certain régime which, he promises, will give results. But it must be religiously carried out for years. The unfortunate thing is that some patients persist in dying before they have given it a thorough trial. The great secret consists in keeping the diet fairly animal proteins, the bowels must act three times and, in the intervals, the life should be simple, moderate exercise, sufficient sleep, and no worry, none should be frequently examined. The editor Dr. L. Duncan Bulkley, writes several of the thoughts that are scattered through the pages. Fortunately his literary style and his knowledge of the piece of advice which we can commend to those investigators who in their blindness fail to perceive of the new hope: "The childhood of a future subject might prove a fertile field for investigation they know. Dr. Bulkley recounts some remedies he has effected on cases of cancer of the which had been given up by less gifted practitioners. All of these had cauliflower "cancers," sometimes down to the "urethra" or "cervix," but they were all cured if the been "curved," but they were all cured if the turned long enough. In one case the patient was saved her red blood corpuscles numbered 4,500 even afterwards she "was in the woods trout-fishing how is the miracle performed? By "being p complete dietetic, hygienic, and medicinal measures vaginal douche." The latter consists of one pin water with a teaspoonful of strong carbolic and borax, some thromboplastin, and a teaspoonful or more. The journal has also reviews and editorial contributions. The first book chosen for review (published twenty-one years ago) is by Dr. Creighton, whom the reviewer hails as "perhaps a persistent runner in America that Rip van woke up. But for real gems one should read authors would recognize their mingled progeny.

pure groups. Dr. Ideker further attempts to explain the specific action of disinfectants by considering what will happen when a disinfectant drug contains numerous reacting groups. These must be arranged on the molecule in a specific manner, and we must also assume that the acceptor groups in the protoplasm of the bacteria are also arranged in a specific manner which differs for each bacterial species. In some cases the arrangement of the reacting groups will fit the arrangement of the acceptor groups, and multipolar contact will be established and a specific germicidal action will result. When the two sets of groups do not fit the action will be much feeble or non-specific. This conception differs in important details from Ehrlich's theory of hapthore groups, and appears to be a real advance, since it is based on the modern physico-chemical views of solution and adsorption.

be attributed to the use of pituitrin. The present communication was based on a series of forty-four cases; most of these had suffered from purulent vaginal discharges and were therefore unsuitable for induction by the ordinary mechanical methods. The technique followed in the majority of cases was that advised by Watson—namely, castor oil one ounce at 6 p.m., quinine hydrochloride gr. x at 7 p.m., enema at 8 p.m., quinine hydrochloride gr. x at 9 p.m., quinine hydrochloride gr. x at 12 midnight. If effective labour pains had not started twelve hours after the first dose of quinine—namely, by 7 a.m.—intramuscular injections of pituitrin were started, with a dose of 1/2 c.cm., and repeating this every half-hour until labour commenced, or 3 c.cm.—that is, six injections—had been given. That was one full course. If labour pains did not start the treatment was repeated again after twenty-four hours. The quinine hydrochloride was given dissolved in  $\pi$  x of dilute hydrochloric acid. The indications for its use included disproportion, primiparity at term, post-maturity, toxæmia, and hydramnios. Twenty-seven of the patients were primigravidae, the others multiparae. Twenty-three of the patients were at term, three were post-mature according to the estimated dates, and eighteen were premature. Out of the forty-four cases, forty were successful—that is, a little over 90 per cent. All the failures occurred in cases where premature induction had been attempted. With regard to the time taken to start and complete labour, counting from the first dose of quinine, the time taken till the onset of labour averaged twenty-nine hours; the average duration of labour was sixteen hours. In premature cases the average time taken till the onset of labour was thirty-nine hours, the average duration of labour being nine hours. In spite of the numerous objections that had been urged against the use of pituitrin, the only unpleasant incidents the speaker had experienced were two cases of tetanic contraction of the uterus, in both cases the spasm was effectively controlled by chloroform, but in one case the child was stillborn. While twenty-six of the patients had suffered from purulent vaginal discharges, only three showed a rise of temperature in the puerperium, and in no case was this prolonged into a second day. In four cases the child had been stillborn; in only one case, however, a case of tetanic uterine contraction, could this be attributed to the pituitrin.

Dr. WILLIAM FORDYCE read a communication on rupture of the uterus following the administration of pituitrin for the induction of labour. The patient, a multipara, was admitted to the Edinburgh Maternity Hospital at term; the cervix was completely taken up, the os slightly open. Several of the previous labours had been difficult, forceps delivery being required. The pelvic measurements were normal. It was decided to induce labour at once, and after three preliminary doses of quinine gr. x three intramuscular injections of pituitrin 0.5 c.cm. were given at half-hourly intervals. After the third injection labour pains commenced; with the first pain the membranes ruptured. Following the occurrence of a long and severe pain, a quarter of an hour after the onset of labour, the patient complained of general abdominal discomfort and dyspnoea and appeared collapsed. Her symptoms were attributed by the house-surgeon to some cardiac weakness and she was treated accordingly, with temporary benefit. When Dr. Fordyce saw her two hours after the onset of labour the clinical features suggested a concealed accidental haemorrhage, more especially as on vaginal examination a considerable quantity of dark-coloured blood escaped, but on passing the fingers through the os, which was by now almost fully dilated, a large tear was found in the postero-lateral wall of the uterus. Immediate laparotomy was performed. On opening the abdomen the placenta and membranes were entirely extruded from the uterus and were found high up under the diaphragm. The foetus, which weighed 9 lb. 11 oz., was lying free in the abdominal cavity with the exception of the head, which still occupied the lower part of the uterus. The rent in the uterus extended upwards from the right utero-sacral ligament towards the fundus. A rapid subtotal hysterectomy was performed, the patient making an excellent recovery. Owing to the number of points of interest raised in the subsequent discussion it was decided to continue this at the next meeting of the Society.

## ELECTROMYOGRAPHIC STUDIES OF VOLUNTARY MOVEMENT.

Dr. F. L. GOLLA brought before the Neurological Section of the Royal Society of Medicine on December 13th a number of electrical records of contracting muscles in the human subject. His special technique for this purpose involved the use of electrodes which would not suffer displacement with movement and which permitted the exclusive recording of the electrical changes in a selected superficial muscle. An electrode, in the shape of an ebonite disc, was devised to fasten on to the skin by suction, and a needle was plunged down through the skin into the substance of the muscle to be investigated. The current from each muscle studied was led off by a pair of these electrodes inserted one above and one below the nervous equator of the muscle, and recorded by means of a galvanometer. A modification of this arrangement permitted the recording of muscle sounds; the place of the needle and of a cork which held it in position in the ebonite disc electrode was replaced by a length of tubing communicating with a microphone, and the microphone current was led through a telephone receiver and by an ingenious device the induced currents were led off to the galvanometer so that the muscle sounds of a pair of muscles could be recorded. The method admitted of the investigation only of superficial muscles, and of only two of these at a time, but by combining the results obtained from various pairs it was possible to obtain some knowledge of the time relations of the activity of all the superficial muscles involved in the specific movement.

He showed a number of records appertaining to the voluntary movements of the ankle-joint, the knee, and the arm, all of which movements involved synergic contraction of anatomically antagonistic muscles. An attempt was made to differentiate between the electromyograms of the two heads of the triceps. It was found that during the early part of the movement of extension the short head of the biceps alone contracted, and not until the forearm was at an angle of about 120 degrees with the upper arm did the long head of the triceps begin to contract vigorously. It was found also that the brachialis anticus began to contract in the movement of flexion after the biceps contraction, and ceased when the forearm was at an angle of 60 degrees with the upper arm. The synergism between the extensor longus pollicis and the flexor carpi ulnaris appeared to be complete, the muscles contracting simultaneously when the thumb was voluntarily extended. Similarly the contraction of the biceps and the supinator longus occurred simultaneously in the movement of supination. Contraction of the two sterno-mastoids in flexion of the head was simultaneous, but on rotation of the head the sterno-mastoid on the side from which the head was rotated preceded by about one-hundredth of a second the moderating contraction of the one on the other side. A very slow movement of rotation of the head appeared, however, not to be accompanied by a moderating contraction of the antagonistic sterno-mastoid. A simultaneous contraction of the deltoid and contralateral erector spinae occurred on voluntary adduction of the arm. The only case that Dr. Golla had been able to study of an apparent antagonism between the two muscles was in the relation between the activity of the biceps and the pronator radii teres in the movements of supination and pronation. That this antagonism was not absolute was, however, shown by the fact that when the wrist was firmly grasped by the observer, if an attempt were made to supinate or pronate against resistance, synergic contraction of both biceps and pronator occurred, the prime mover showing a greater amplitude of oscillation in the electromyogram of each movement.

Dr. Golla went on to discuss the relation of synergic contraction in voluntary movement to the tonic reflexes which had been studied in decerebrate animals, a relation which he found to be not at all clear. His records left it an open question whether anything corresponding to the inhibition of antagonists in the spastic reflex animal took place during voluntary movement. They showed that so far as cortical innervation was concerned synergism was

included among the new cases not only the primary notifications but also any other new cases coming to the notice of the medical officer of health. This would appear to refer to deaths from tuberculosis which had not been notified during life. Information this year is asked for where there is any excessive incidence of or mortality from tuberculosis in any particular occupation. Under the heading of notifiable diseases information is sought as to the influence of domestic overcrowding upon the incidence of notifiable diseases, especially scarlet fever, diphtheria, and here notifiable, of measles, differentiating between cases moved to an isolation hospital and those nursed at home. As in former years, the Registrar-General will furnish medical officers of health with certain statistical information about the end of February, 1924, and emphasis is laid on the importance of an early issue of the annual report, which is considered should be completed by the middle of April. A few years ago, after conferring with the Society of Medical Officers of Health, the Minister of Health decided that once in about every five years there should be issued an extended "survey report," and that in the intervening years the document should be styled an "ordinary report." That for 1923 comes under the latter category.

#### COURT OF INQUIRY INTO THE INSURANCE CAPITATION FEE.

The Court of Inquiry set up by the Minister of Health in connexion with the terms of remuneration for the insurance medical service after January 1st, 1924, will hold its first session for the taking of evidence on Friday, January 4th, at 10.30 a.m., at the Ministry of Health. A memorandum, with appendices, drawn up on behalf of insurance medical practitioners by a special subcommittee of the Insurance Acts Committee, has been completed, and it will, we expect, be possible to publish this in the *STANDARD* to the next issue of the *JOURNAL*; it is also hoped that memorandums by the Ministry of Health and the General Council of Approved Societies will be available for publication in the same issue. The subcommittee of the Insurance Acts Committee, which has prepared the case on behalf of insurance practitioners, consists of Drs. Brackenbury, Bone, (Farde), Dain, and William-Freeman, together with the Medical Secretary and Deputy Medical Secretary, and the memorandum has been revised by the subcommittee with the assistance of legal advisers and of Dr. A. L. Bowley, Professor of Statistics in the University of London. In these circumstances a *STANDARD* is not published with this issue of the *JOURNAL*.

#### THE NEW REGULATIONS FOR THE D.P.H.

The new regulations of the General Medical Council for the Diploma in Public Health will apply after January 1st next. Under the old rules candidates for the diploma might enter upon the stated curriculum at any time after obtaining a registrable qualification in medicine and surgery. It was required that the curriculum should last not less than nine calendar months, and should include four months' stay in a laboratory, six months' practical study of the duties involved by public health administration, and attendance at least twice weekly for three months on the practice of a hospital for infectious diseases. The new rules require that a period of not less than two years should elapse after obtaining a registrable qualification before admission to the final examination for a public health diploma. The curriculum must extend over not less than twelve calendar months; at least five months must be given to practical laboratory instruction in bacteriology and parasitology, and in chemistry and physics.

The new Parliament is to assemble on Tuesday, January 8th. The first duty of the House of Commons will be the election of Speaker. This has to be made afresh by each Parliament; but there is no reason to doubt that Mr. Whitely will again be called to the chair. After that the members will be sworn in, and the State opening by the King will not take place until Tuesday, January 15th. This ceremony will, in the ordinary course, include a King's Speech, which usually forecasts the business of the session. In the present instance the situation is peculiar, inasmuch as it is understood to be the intention of the Labour party, upon the motion for an address in reply to the speech, to move a vote of no confidence in the Government. Mr. Asquith's declaration at a meeting of his party indicated that the Liberals would be asked by him to support such a vote. Assuming that Mr. Baldwin's ministry is defeated there will be an interval of a few days for the formation of a new ministry by, as is anticipated, Mr. Ramsay MacDonald as the head of the party (the Labour party) next largest in that of the Conservatives. As no purpose would be served by any lengthy general debate on the vote of no confidence will be taken promptly, that the division will take place on Thursday, January 17th, and that the new ministry would be in office in the following week. As the Conservatives and the Liberals in opposition would, if on any occasion they voted together, be in a majority, it is impossible to forecast the probable course of events.

#### THE PARLIAMENTARY TRIANGLE.

The new Parliament is to assemble on Tuesday, January 8th. The first duty of the House of Commons will be the election of Speaker. This has to be made afresh by each Parliament; but there is no reason to doubt that Mr. Whitely will again be called to the chair. After that the members will be sworn in, and the State opening by the King will not take place until Tuesday, January 15th. This ceremony will, in the ordinary course, include a King's Speech, which usually forecasts the business of the session. In the present instance the situation is peculiar, inasmuch as it is understood to be the intention of the Labour party, upon the motion for an address in reply to the speech, to move a vote of no confidence in the Government. Mr. Asquith's declaration at a meeting of his party indicated that the Liberals would be asked by him to support such a vote. Assuming that Mr. Baldwin's ministry is defeated there will be an interval of a few days for the formation of a new ministry by, as is anticipated, Mr. Ramsay MacDonald as the head of the party (the Labour party) next largest in that of the Conservatives. As no purpose would be served by any lengthy general debate on the vote of no confidence will be taken promptly, that the division will take place on Thursday, January 17th, and that the new ministry would be in office in the following week. As the Conservatives and the Liberals in opposition would, if on any occasion they voted together, be in a majority, it is impossible to forecast the probable course of events.

A discussion on the use of vaccine therapy will take place at a joint meeting of the Sections of Medicine, Pathology, and Therapeutics and Pharmacology of the Royal Society of Medicine at 4.30 p.m. on Tuesday, January 8th. It will be opened by Sir Almonro Wright, and it is expected that Sir Thomas Horder and Professor Dwyer of Oxford will take part in it. The next sessional meeting of the Royal Society of Medicine will be held on Wednesday evening, January 16th, when the Fellows, Associates, and their friends will be received by the President and Lady Hale-White at 8.30. Dr. Arnold Chaplin will give a brief discourse on famous medical men of the eighteenth century, with lantern illustrations of portraits, at 9 o'clock.

At the November meeting of the Nottingham  
 Chirurgical Society, held at the Society's rooms, S  
 Street, Mr. ALEXANDER FLEMING, F.R.C.S., of the In  
 Department, St. Mary's Hospital, London, gave a p  
 antiseptics. He detailed the tests for antiseptic po  
 conditions similar to those found in an infected wo  
 comparative uselessness of known antiseptics and the  
 cence in the body were strikingly illustrated. Th  
 demonstrated experiments which showed the  
 mechanism of the body, and the adverse influen  
 centics on these defences against bacterial invasion.

§ Collm

WEST OF SCOTLAND FOREIGN S

This club, which consists of members resident in the West of Scotland, was formed in 1892. The Grosvenor Restaurant, Glasgow, the President, Colonel A. D. Moore, C.B., president of the East of Scotland Medical Club, Dr. W. T. Gardiner, and Professor Archibald Main, Glasgow, Dr. Dewar, in proposing that it was an honour both to the Foreign Service Club of the East and to the opportunity of expressing the club should flourish and prosper for him only those episodes which pleasant memories had been salved by the passing into oblivion of a civil servant, he had had an and his colleagues in various circumstances that the profession had in all its devotion, courage, and self-sacrifice that the club which had so much to offer should sustain its comradeship which had been for so long. The President, in his reply, said that the club was a credit to the Territorial experience, his

...which he hoped  
...the 'celestial'...

The following table shows the results of the annual meeting of the League, held at the Royal Infirmary of Edinburgh, on December 10, 1921, when Mr. J. H. Paton, Organizing Secretary of the League, presided over a large attendance. The annual report, stated that a large number of contributions from the employees of the League had been received, and that the League was in a position to make a large contribution to the annual meeting of the League, which was held at the Royal Infirmary of Edinburgh, on December 10, 1921, when Mr. J. H. Paton, Organizing Secretary of the League, presided over a large attendance. The annual report, stated that a large number of contributions from the employees of the League had been received, and that the League was in a position to make a large contribution to the annual meeting of the League, which was held at the Royal Infirmary of Edinburgh, on December 10, 1921, when Mr. J. long way ahead of the £8,000,000 years ago, and had brought the II bought at least of any other the support derived from man Crolo, K.C., one of the Managers said that the patients treated 15,043 during the past year, as during the previous year; but the patients, showing an increase of 4 economies perfectly consistent had been made and the cost per £13 11s 4d, a decrease of £3 2s

## Reviews.

### PROGNOSIS AND TREATMENT.

The *Index of Prognosis* is a companion to the *Index of Treatment and Index of Differential Diagnosis* produced by the same publishers, and that it has fulfilled a useful purpose is apparent from the fact that it is now in its third edition.<sup>1</sup>

To obtain accurate information regarding end-results is among the most unsatisfactory of medical pursuits. The more difficult the type of case, and therefore, one would imagine, the more urgent the necessity for accurate knowledge of prognosis and the results of treatment, the more elusive is the attempt to obtain reliable information. It is perhaps natural that there should be this difficulty. Few are disposed to go out of their way deliberately to publish bad results, for the reason that most likely adverse criticism will be aroused and so the reputation of the reporter will suffer. It is with unusual interest, therefore, that we have observed the method of dealing with the question attempted by the writers of this publication.

The diseases which come under discussion are arranged in alphabetical order, and facility of reference is thereby afforded; the compilation of morbid conditions is wonderfully complete, and we have been unable to discover the omission of any common and important disease.

The title of the work is not an exact indication of its contents; the volume is more than an index of prognosis and end-results of treatment, for it includes considerations of interest and value in connexion with treatment, pathology, and etiology. It is better that it should be so, and these authors who have presented their subject from the broad point of view are the most interesting of the various contributors.

In certain of the contributions there has been a tendency to limit the source from which the end-results of treatment have been obtained. A considerable proportion of the results have been derived from individual experience and the records of two large London hospitals, and these sources are somewhat too narrow to supply the information for a work of this description, for, if it is to be of value to the specialist, it must be a compilation of the widest possible collections of home and foreign literature. We realize how immense would be the task were this idea carried to fulfilment, but where certain sections of the book are concerned the sources of information have been unwisely confined.

The matter actually presented is excellent, and, taken as a whole, a very fair solution of the problem of prognosis is presented. We are less satisfied with the information which is afforded regarding end-results of treatment, but, as we have attempted to explain, this must always remain a difficult and somewhat delicate line of investigation.

That section of the volume which deals with goitre is disappointing. The classification adopted is an unusual one, and it is difficult to understand the pathological standards upon which it has been based. It is surely incorrect to classify "adenomatous and cystic goitre" under a common heading, and the term "papilliferous goitre" seems to us unhappy. The statistics dealing with the operative treatment of exophthalmic goitre have not been brought up to date, and we would have been glad of more information as to when operation is indicated and as to the dangers of interference during periods of toxicity.

After perusal of the volume the reader naturally asks himself the question, Does this book fulfil the object for which it presumably has been written—namely, to supply in accessible and necessarily condensed form reliable information upon questions of prognosis and results of treatment? We think the answer must be that the value will depend upon the purpose of the inquirer: the volume is not of much help to the specialist, the subject-matter being too condensed for his purpose and the sources of information somewhat limited, and also in certain instances

out of date. On the other hand, the practitioner will find that the volume is a compilation of reliable and interesting information such as would be inaccessible to him except by long and detailed search through the literature. In this last respect, therefore, we consider that the volume is a useful contribution to medical literature.

### LIGHT AND COLOUR.

Few advances in modern science are more absorbing or more far-reaching in their possibilities than those connected with the visible and invisible spectrum. The full significance of this is well exposed in *Light and Colour*<sup>2</sup> by Dr. R. A. Houstox, lecturer on physical optics in the University of Glasgow. The subject is exciting much popular interest at present, and the book has been written primarily for amateurs and in answer to questions addressed to the author by photographers, medical students, and members of the public generally. At the same time, as is stated in the preface, its contents are of interest and value to the serious student; and there is much in it that has not hitherto appeared in other works on the subject.

The opening chapter contains an account of the spectrum and its discovery by Isaac Newton in 1666. From this the subject is developed in various directions historically. About five hundred years before the Christian era Pythagoras discovered the octave on vibrating strings, which fixed the musical scale. Some two thousand years later Newton applied the musical scale to the spectrum, influenced, as Dr. Houston surmises, by Kepler's work on the *Harmonices Mundi*, or the Harmonies of the Universe, and the famous doctrine of the music of the spheres. The mediaeval tradition of harmonical progression survived for a long time in the textbooks of algebra, and the opening chapter has much to say on its influence on astronomers from the earliest time and the complicated reasonings to which the doctrine of the music of the spheres gave rise.

All this comes as an introduction to the theory of light as evolved after the discovery of the spectrum. Newton believed that the colours of the spectrum consisted of particles of different size, the red rays being the largest and violet rays the smallest. This theory was challenged by Thomas Young, who held that they consisted of waves of different lengths, and these two explanations of the spectrum are discussed by the author in a chapter on the nature of light, in which he leads the reader on to Einstein and relativity and to the quantum. Dr. Houston's attitude towards these modern developments, as affecting the science of physical optics, is non-committal. He remarks that—

"it is a depressing experience to study the utterances of philosophers on Einstein or to read a popular discussion on the subject in one of the literary journals. The participants have as much hope of getting near the gist of the matter as the proverbial blind man in a dark cellar looking for a needle that is not there."

With regard to the quantum, which keeps cropping up in different fields of investigation, always in association with light or radiation of appropriate wave-length, he notes that the precise connexion between them is not known, and that opinions vary from the radical view that there is something seriously wrong with the present theory of light to the conservative view that the wave theory is all right and that the quantum is the amount of energy liberated or absorbed in some internal change in the atom. Newton's corpuscular theory thus appears again as a working hypothesis to those who hold that the process of radiation as a whole depends in part on the movement of electrons. A stream of electrons, for example, becomes a corpuscular radiation in the x-ray bulb.

There is an illuminating chapter on the use of invisible rays in war and secret signalling, on  $\alpha$  rays and the rays emitted by radium, and on wireless telegraphy, which depends on electro-magnetic waves of the same nature as light waves, differing only in being longer and varying in size from 0.16 cm. to hundreds of kilometres in length. The original spectrum of Newton has thus in modern science grown enormously from the wireless waves beyond the infrared to the radium rays beyond the ultra-violet. The visible

<sup>1</sup> *Index of Prognosis and End-results of Treatment*. By various writers. Edited by A. Rendle Short, M.D., B.S., B.Sc., Lond., F.R.C.S. Eng. Third edition. Bristol: John Wright and Sons, Ltd.; London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd. (Roy. 8vo, pp. xi + 554. 45s. net.)

<sup>2</sup> *Light and Colour*. By R. A. Houston, M.A., Ph.D., D.Sc. London: Longmans, Green and Co. 1923. (Demy 8vo, pp. 175; 71 figures, 8 plates and frontispieces. 7s. 6d. net.)

and now become possible to undertake some extensions. Small wards were to be added at once to the ear, nose and throat department at a cost of £12,000. A new department would be built at a cost of about £10,000. When it was built and equipped it would be the centre of a preventive campaign. There appears to have been a steady increase in the incidence of this disease: in 1911 only 1,541 cases were treated, in 1919 the number had risen to 4,250, in 1920 to 7,352, in 1921 to 11,231, and in 1922 to 18,506, which was equivalent to 397 cases per 10,000 of the population. It is feared, moreover, that there is a far greater prevalence of the disease than the official figures indicate, and that if active preventive measures are not quickly taken there is said to be a distinct risk of 60 to 80 per cent. of the population of Calcutta being infected within six or seven years.

#### LIVERPOOL CAMPAIGN.

The fifth annual report of the Bombay League for combating venereal diseases contains a carefully compiled statistical record of the work of the League during the twelve months ending January 1st, 1923. There was a considerable increase in the number of patients treated in the dispensary, the average daily attendances of new and old cases being between seventy and eighty. The source of infection is traced whenever possible, and the whole of the work is conducted in close co-operation with medical practitioners and various institutions. The pathological investigations are carried out at the Grant Medical College Bacteriological Laboratory, and the Wassermann tests are continued for two years after the cessation of treatment. Post-graduate teaching is provided and the general public is supplied with literature.

#### KRISHNAPATNAM HOSPITAL, MYSORE.

The report for 1922 of the Krishnapatnam Hospital, Mysore, contains evidence of the excellent work that is being carried out there. A total of 53,157 patients were treated during the year, of whom 2,227 were in-patients; it is worthy of special comment that fifty were suffering from malignant growths. There is a prevalent idea that malignant disease is extremely rare in India, but it would seem that all parts of the country are not equally immune. In the course of the year 1,069 major operations and 1,240 minor operations were performed. The work comprised the treatment of eye diseases (7,604 cases), digestive troubles (5,866 cases), malaria (4,767 cases), ear diseases (4,172 cases), respiratory diseases (3,562 cases), injuries (1,188 cases), and rheumatism (2,047 cases). There were 1,257 cases of venereal disease, 595 of liver disease, 623 of dysentery, and 196 of all forms of tuberculosis. Dr. Mahomed Usman, the superintendent of the hospital, is to be congratulated on the valuable services rendered by this institution.

### Correspondence.

#### RECURRENT OR HABITUAL DISLOCATION OF THE SHOULDER-JOINT.

SIR.—To your issue of December 15th (p. 1132) Mr. A. S. B. Bankart contributes an interesting article upon recurrent or habitual dislocation of the shoulder-joint, and puts forward certain suggestions as to causation and treatment of this condition. In November, 1919, I read a paper on this subject at the meeting of the British Orthopaedic Association, and in May, 1920, the *Journal of Orthopaedic Surgery* published an article embodying this paper. I then reported that I had performed a deltoid flap operation upon a number of patients whose joints had been dislocated from twelve to twenty-nine times and that I was convinced of its value. Between that date and July, 1922, I had an opportunity of performing the operation on three other cases—two in my own hospital clinic and one at Manchester Royal Infirmary by the kind invitation of Professor Telford. These patients had each suffered more than eleven dislocations, and one of them had been dislocated six times since a capsulectomy. There has only been one case of redislocation in these seven cases since the deltoid flap operation was done, and in this case the deltoid flap operation was a capsulectomy.

#### NEW WING FOR VICTORIA INFIRMARY, GLASGOW.

The annual meeting of the Victoria Infirmary of Glasgow held on December 6th. Lord Provost Moncreiff, who presided, stated that it was proposed to erect a new pavilion for patients, together with additional accommodation for the Board of Governors, said that the erection of the pavilion would be commenced early in 1924, and when finished would provide 105 new beds. Their maintenance would involve an additional £10,000 yearly.

### India.

#### HONORARY STAFF TO CIVIL HOSPITALS.

A Surgeon-General, addressing a delegation of the Medical Union, at Karachi, on November 14th, expressed himself as being strongly in favour of appointing honorary staff in civil hospitals wherever possible. The necessity would have to be gradual to avoid dislocation of hospital routine and might conveniently start with the appointment of specialists—for example, in ophthalmology. It is also hoped to see an extension of post-graduate hospital work, including residential hospital appointments for the very qualified.

#### CO-ORDINATION OF MEDICAL RESERVE.

A recent conference of medical men from almost all parts of India was held in Calcutta, with a view to devising a scheme of communication between research workers in different provinces. It is felt that there is a great need for those who are engaged in the investigation of the uses of disease, or of curative and preventive methods, could be in far closer communication than is at present the case, so as to avoid overlapping of effort and waste of

#### LADY READING HOSPITAL.

The building of the Lady Reading Hospital for Women and Children, which is to replace the present Lady Dufferin Hospital, now inadequate for the work, is making good progress and should be ready for occupation by next May. The Lady Dufferin Hospital will then become an infant welfare centre, but will retain its present out-patient department for use in connexion with the wards of the hospital, of which eight will be private and self-maintained, and used for paying patients. The whole hospital will be equipped and staffed on the most modern lines. It will be under the superintendence of Dr. Houlton of the Women's Medical Service, who is at present in charge of the Dufferin Hospital. A special feature of the work will be the systematic training of Indian ladies as qualified nurses. The well known interest of the Countess of Reading in this work is further exemplified by her offer of medals for competition in Delhi, and in each Indian State, during the baby week of 1924, the condition being made that the mothers must have been attending child welfare centres.

#### THE KALIA-ZAR ALEXAND.

The Bengal Government has issued a statement dealing with Kalia-zar in Bengal. Three hundred men

spectrum in fact forms only a small portion of the complete spectrum. In this chapter on invisible rays the author also describes the optical telephone, speaking films, and the optophone for enabling the blind to read by means of the sounds emitted in passing five little spots of light arranged in a row, known as the scala, along a line of printed type.

The constitution of the atom and the stars, the infinitely small and the infinitely great in the physics of the universe, and the way in which the most important recent work on light and the spectrum is applied to our knowledge of these, form the subject of another chapter. It is followed by a chapter on the primary colours and their combinations, which together with a chapter on colour photography and stereoscopy is of special interest in connexion with painting, photography, and colour printing. A chapter on colour blindness describes in clear language the scientific and practical aspects of this important subject.

In another chapter the author indulges in many interesting speculations on the light of the future and the relative commercial values of the glow lamp, the incandescent mantle, the arc lamp, and the half-watt lamp. The light of the future, he says, is a field in which "we require research and more research and more research still." For, taking it at its lowest, he informs us that "when a householder wishes 2s. worth of electric light he has to take £2 18s. worth of useless dark heat along with it." Consequently "the discovery of a perfect light, the light that is all light and is unaccompanied by useless dark heat, is one of the most pressing problems of applied science." In Nature the firefly emits such a light—that is to say, the energy radiated all lies in the middle of the visible spectrum; and from this fact is deduced a hope that the perfect light may eventually be discovered.

Other chapters of the book deal with photochemistry and allied effects, and with phototherapy. In the first of these a good account is given of the bactericidal action of light and its restriction to the ultra-violet radiations, and of the photosynthetic action of chlorophyll. Phototherapy, radiotherapy, and heliotherapy are discussed clearly and scientifically. The value of sunshine in the treatment of rickets is recognized and explained tentatively as probably due to inflammatory or subinflammatory processes in the skin, which produce the fat-soluble vitamin A by a photochemical reaction set up by sunlight and ultra-violet light. The author, however, is unable to explain the value of sunshine in the treatment of tuberculous affections as carried out at Leysin in the Swiss Alps; for he remarks that, if it is a case of selective action on the bacilli, the group of radiations which penetrate the skin are not bactericidal, while on the other hand the bactericidal group are neither present in sunshine nor do they penetrate the skin. Incidentally it may be mentioned that Dr. Rollier and his clinical assistants, although they recognize the difficulty raised by these facts, hold that sunshine has a bactericidal action, when prolonged over long periods and at maximum intensities. In any case they regard sunshine as a powerful adjuvant to the natural defences of the human body, and capable of evoking changes within it, which increase its bactericidal properties. They have had remarkable results, especially in cases of tuberculous disease of the knee and foot and other structures near the surface of the skin or exposed by open sores. Patients suffering only from pulmonary tuberculosis are not admitted to Dr. Rollier's clinics. The Leysin theories are explained in a physical and biological study of light, by Dr. Rosselet, which appeared in the *Revue Suisse de Médecine* in February and March last year.

Dr. Houston's final chapter on the psychology of colour will be read with interest as it suggests to the brain worker and others possibilities of effects of colour environment on the work they produce, although the theory that different colours excite different emotions or mental states led nowhere when put to the test of experiment. The highly scientific character of the volume is relieved by much philosophical and speculative thought. The amateur will find little difficulty in grasping from its perusal the trend of modern science in the domain of physical optics; but, unless he is already equipped with some knowledge of applied mathematics and physical chemistry, he may not find it easy to follow the details of some of the chapters. Taken

as a whole, however, it is an intensely stimulating book and well up to date, admirably and clearly illustrated and printed. The medical practitioner will find in it much food for thought. In these days of radiotherapy he cannot afford to neglect the study of light and colour in their scientific aspects, and for this purpose Dr. Houston's volume will prove a valuable addition to his library table.

### ENDOCRINE THERAPEUTICS.

THE textbook of diseases of the endocrine glands<sup>3</sup> Dr. HERMANN ZONDEK, professor in the University of Berlin, has written for students and practitioners is an excellent summary of our present knowledge of this difficult subject. The outlook is mainly clinical and the book gives a general account of the causation, nature, and treatment of the chief diseases which it is recognized are caused by deficiency or overaction of the endocrine organs. The book contains 170 illustrations, most of which are reproductions of photographs of typical cases of the diseases described.

After a general discussion of the laws governing endocrine secretion, the bulk of the book is devoted to the description of the individual diseases, the chief being exophthalmic goitre, myxoedema and cretinism, tetany, obesity, diabetes insipidus, acromegaly, gigantism, dwarfism, osteomalacia, Addison's disease, status lymphaticus, and disorders of the genital functions. The omission of any mention of the pancreas in relation to diabetes mellitus seems inexplicable.

The author confines himself to the clinical aspect of the problems dealt with, and avoids all discussion of purely physiological questions; this restraint has made it possible to keep the size of the book within reasonable dimensions; the bibliography is restricted to a useful list of thirteen pages of selected and recent references. In a discussion of the relation between endocrine secretion and the autonomic nervous system an account is given of the theories of Eppinger and Hess regarding vagotonia and sympathicotonia, and the tests for showing the existence of each of these conditions are described. The author does not, however, accept these theories unconditionally, but points out that the relation between the endocrine and autonomic nervous systems is extremely complex. He does not look on the hormonal system as the uncontrolled dictator of the bodily functions, but considers that its functions are probably equal to those of the autonomic nervous system and that either system can profoundly modify the activities of the other. In particular he points out that in actual practice it is very difficult to find cases that can be regarded as typically vagotonic or sympathicotonic.

In the portion devoted to the discussion of the different types of endocrine diseases a full description of the etiology, symptomatology, prognosis, and therapy of each is given. The symptomatology is dealt with very fully and the excellent illustrations are an outstanding feature of the book. The portions dealing with endocrine therapy are of very particular interest. The bulk of the literature on this subject is, of course, very uncritical and, to say the least, highly optimistic. In writing a summary of such literature the temptation is great to yield to the pervading facile optimism and to describe series after series of remarkable cures. Fortunately Professor Zondek has done a considerable amount of original work on endocrine therapy, and has tested the action of numerous endocrine products by delicate metabolism experiments. Consequently he treats the whole subject with a healthy scepticism and distinguishes clearly between subjective and objective evidence. His general attitude is thus defined (p. 38): "Unfortunately the therapeutic results obtained in diseases which do not depend on thyroid insufficiency cannot in any way be compared with those obtained in hypothyroidism. This must be strongly emphasized." He goes on to point out the innumerable difficulties attending the extraction from a gland of its specific hormone, and suggests that in many cases the trade preparations do not really contain the specific gland products.

The account of the history of the treatment of

<sup>3</sup> *Die Krankheiten der endokrinen Drüsen. A Manual for Students and Practitioners.* By Dr. Hermann Zondek, Professor in the University of Berlin. Berlin: Julius Springer. 1923. (Sup. roy. 8vo, pp. vii + 316; 173 figures. Unbound, 3.85 dollars; bound, 4.20 dollars.)

exophthalmic goitre is excellent evidence of the uncertainty of some of the positive results claimed for endocrine products. Preparations of the ovaries, the pancreas, the suprarenals, the posterior lobe of the pituitary, and of the thymus have all been recommended, but all these measures possess to-day only an historic interest since in no case has it been shown that they can produce any objective measurable influence upon the disease. The author favours the use of potassium iodide in doses of a few milligrams a day, and produces evidence that this treatment can reduce the basal metabolism in exophthalmic goitre by 30 per cent.

In the discussion of the treatment of myxoedema and obesity Professor Zondek gives an account of some interesting experiments he has performed to estimate the relative value of thyroid preparations. He made metabolic measurements in a series of cases of hypothyroidism before and after treatment with a series of proprietary preparations of thyroid. He concluded that thyreoglandol and thyroideaopton were devoid of any action on metabolism, and that the activity of the other preparations showed considerable variations. This plan of obtaining a quantitative estimate of the activity of thyroid preparations appears to have great possibilities, for obviously a method of standardization that is based on human metabolism measurements is in many ways much more satisfactory than the usual method of measuring the action of preparations on the metamorphosis of tadpoles. He describes similar tests made with ovarian extracts in cases of deficient ovarian secretion. In castrated women ovarian grafting produced a well marked increase in oxygen consumption, but he found that none of the preparations of ovarian extracts produced any demonstrable effect on metabolism in similar cases.

An interesting account is given of the results of rejuvenation by Steinach's operation (ligature of the vas deferens), and in this case also the author has applied the definite scientific test of metabolism measurements. He finds that the Steinach operation produces a definite rise in the rate of metabolism, but that this passes off after a month or so, and he concludes that the beneficial effects are in the nature of a transitory stimulus. Professor Zondek's general conclusions (p. 276) regarding the therapy of sex gland deficiency are that "the treatment of conditions of sex gland insufficiency is on the whole a thankless task. The hope that treatment with specific substitution products would produce in this case results at all comparable with those achieved in hypothyroidism has, broadly speaking, been disappointed." He holds that the effects of suggestion constitute a very serious source of error in considering the effects of endocrine therapy in sexual deficiency, and he quotes cases where temporary positive results have followed the injection of sterile saline.

All interested in endocrine disease should study Professor Zondek's work, for it contains a full and well illustrated description of the chief types of endocrine disease, and in addition gives a reasoned and critical account of the results obtained with endocrine therapy in these diseases. Unfortunately, this last feature is sufficiently rare to be remarkable amongst the clinical literature dealing with endocrine diseases. If the author's method of treating this subject were only more general the subject of organotherapy would show more resemblance to a progressive branch of therapeutics and less resemblance to sympathetic magic.

#### CALMETTE ON TUBERCULOSIS.

The success, both in France and elsewhere, of CALMETTE's great book on tubercle was so immediate that the first edition became exhausted within a few weeks of publication, and a second edition followed within a commendably short time.\* The principal addition consists in an important chapter dealing with various laboratory researches into the drug treatment of tuberculosis. This chapter, entitled "Attempts at Chemotherapy in Tuberculosis," is a comprehensive survey of recent efforts to discover some bactericide which could destroy the bacillus *in vivo* as arsenical compounds do spirilla and trypanosomes.

\* *L'Infection Bacillaire et la Tuberculose chez l'homme et chez les animaux.* By A. Calmette. Second edition. Paris: Masson et Cie. (Roy. 8vo, pp. vi + 644; 31 figures, 25 plates. Fr. 53 net.)

The majority of these attempts have proved failures; nevertheless Calmette is of opinion that certain suggestions are valuable and worth further study. Although he concludes with the observation that "despite the great number of attempts made to discover among chemical agents a substance capable of arresting the development of experimental tuberculosis in the guinea-pig and the rabbit, these efforts have been in vain"; yet this, he says, is not a reason for discouragement. Some of the drugs that have been tried (notably those with iodized compounds) even if they do not appear full of promise give definitely favourable results. The practice of injecting at random certain chemicals into patients with the vague hope of discovering a specific activity should be condemned. "Experimentation alone, methodically conducted upon animals sensitive to tuberculosis, will enable us to explore with profit the immense perspectives that chemotherapy offers."

Our quotations are from the authorized English translation<sup>†</sup> by SOPER and SMITH, who, realizing the need of bringing this work before the English-reading public, have earned our gratitude by the way they have accomplished their task. Two apparently minor points will illustrate the care which has been devoted to this translation; all the references have been verified and set out in a manner that is a distinct improvement on the French editions, whilst the index enables the reader to turn to particular subjects in the text far more readily than in the original. The colour-plates fall scarcely at all below those of Masson, the publishers of the French edition.

Calmette's style is singularly clear and direct, and his translators have taken his sentences and turned them almost word for word into English. He is one of the few French authors with whom this is possible without producing a confusion of idioms, and, though the result is not elegant, the meaning is seldom in doubt. On page 354, describing the conditions under which the sale of tuberculous pork is permitted, the translators have added after the phrase "Assistance Publique" "(Department of Charities of Paris)." In the original, however, there is no mention of Paris, and the paragraph appears to refer to the abattoirs of Buenos Aires.

Lapse of time has not diminished our appreciation of this remarkable book, and we congratulate the publishers and translators of the English version on having rendered it accessible to a large and eagerly expectant public.

#### MONTAIGNE AND MEDICINE.

THE medical profession has always numbered many admirers of that most ingenious and ingenuous philosopher, Michel Seigneur de Montaigne, whose delightful *Essais* are best known to English readers through the translations of Florio and Charles Cotton. Dr. J. S. TAYLOR has reprinted, in an attractive little volume entitled *Montaigne and Medicine*,<sup>\*</sup> a serial article which appeared last year in three successive numbers of the *Annals of Medical History*. He presents us with a full account of the medical aspects of Montaigne's life and works, illustrated by copious extracts from the essays and the travel diary.

Montaigne, as every reader of Osler's textbook of medicine knows, was a sufferer from gout and renal colic, of which he has left a classical description, and it was in order to seek relief from his symptoms, as much as to enlarge his mind, that he made an extensive tour through Europe, visiting the spas of France, Germany, Italy, and Switzerland. Though keenly alive to the foibles of the doctors of his day, and the absurdities of the contemporary pharmacopoeia, Montaigne readily submitted himself to the ministrations of physicians whom he regarded as learned and eminent, and in Dr. Taylor's opinion he must have

\* *Tubercle Bacillus Infection and Tuberculosis in Man and Animals.* By A. Calmette. Authorized English translation by Willard E. Soper, M.D., and George H. Smith, Ph.D., Baltimore, U.S.A.: Williams and Wilkins Co. 1923. (Roy. 8vo, pp. xxii + 624; 31 figures, 25 plates. Price: U.S. 5 dollars; Canada, Mexico, and Cuba, 6 dollars; other countries, 8.50 dollars.)

† *Montaigne and Medicine. Being the Essayist's Comments on Contemporary Physic and Physicians. His thoughts on many natural matters relating to life and death; an account of his bodily ailments and peculiarities, and of his travels in search of health.* By JAMES SPENCER TAYLOR, M.D., F.A.C.S. London: Humphrey Milford, Oxford University Press. (Post 8vo, pp. xix + 244; 33 plates. 12s. net.)

and, Dec. 15th.  
M. Kelso Ford.

made an ideal patient. Moreover, he was so keen an observer and recorder of all natural phenomena, including those of disease, that his biographer thinks he would also have been eminently fitted to practise medicine. Remembering his motto "Que sais-je?" we may perhaps agree. Apart from the account of his own illness, several passages in his works show Montaigne's intelligent interest in medicine, such as his description of the spas at Plombières, Lucca, and Viterbo, the miraculous cures at Loreto, and his allusions to contemporary physicians such as Sylvius, Paracelsus, and Felix Platter.

The volume is pleasantly illustrated with portraits of Montaigne and facsimiles of his handwriting; also with photographs of places, mainly in Italy, visited by him on his travels, and views of his family castle in Périgord, to which he retired at the close of the foreign tour, in order to devote himself to the study of philosophy.

## MEDICINAL AND DIETETIC PREPARATIONS.

### *Sulphuretted Hydrogen Soloids.*

CHEMICAL reagents in the form of prepared charges have been found exceedingly useful, both for work at home as well as for use in travelling. They were designed originally for particular applications, but from time to time ingenuity has been exercised to produce them in a form more adaptable to general use. In this direction Messrs. Burroughs, Wellcome and Co. have played a leading part. Their series of "Soloid" reagents includes one for the generation of sulphuretted hydrogen. The soloids for this reagent consisted formerly of a pair, containing respectively zinc sulphide and oxalic acid. They have effected an improvement on this combination, and the sulphuretted hydrogen reagent is now contained in a single soloid of aluminium sulphide. This substance generates sulphuretted hydrogen under the action of water alone, the by-product being aluminium hydroxide, the presence of which is seldom disadvantageous for the purpose of the test. We have examined a sample of the soloids and found them to react well. Each soloid will saturate ten cubic centimetres of water with sulphuretted hydrogen.

## KING EDWARD'S HOSPITAL FUND FOR LONDON.

A DISTRIBUTION meeting of the President and General Council of King Edward's Hospital Fund for London, for the purpose of awarding grants to the hospitals and convalescent homes for the present year, was held on December 18th, with the Prince of Wales in the chair.

Lord REVELSTOKE (honorary treasurer), in reporting the amount received for general purposes, said that this time last year he had expressed the hope that the income to be derived from the munificent legacies of Lord Mount Stephen and Sir Thomas Sutherland would form the nucleus of a permanent increase in the distribution. The Fund had already received a large part of this increased income. The total income from all investments reached £145,000 this year, as against £114,000 in 1922. On the other hand, ordinary legacies had decreased, although for the past twelve months they still reached the substantial figure of £47,000. The net result was that the Fund was able to distribute £235,000. Taking all the sources of income into consideration, there was every hope that this large sum would be provided very nearly, if not quite, out of the current income of the year.

Sir WILLIAM COLLINS, in making the annual statement on behalf of the League of Mercy, said that so far as they could tell from the subscriptions at present received, £14,000 would be handed over to the King's Fund before the end of the year. This would make a total sum of £353,000 handed over to the Fund since the foundation of the League. Adding the grants made to hospitals outside London, the total came to £407,682.

Mr. LEONARD COHEN presented the report of the Hospital Economy Committee on recovery branches of London hospitals, advocating the wider adoption of these as a valuable form of hospital extension.

### *Grants to Hospitals and Convalescent Homes.*

Sir COOPER PERRY presented the report of the Distribution Committee. The sum allocated this year was £233,000, and the need of maintenance grants had been the first considera-

tion. Only in exceptional cases were they prepared to assist in new schemes of improvement or extension, and the amount so expended this year was £30,100. The total grants to maintenance had amounted to £202,900.

Lord SOMERLEYTON (honorary secretary) presented the schedule containing the detailed list of awards to hospitals (including recovery and convalescent branches).

The larger sums awarded include £14,000 to the London Hospital, £11,500 to Guy's Hospital, £10,000 to St. Bartholomew's Hospital, £9,500 to St. Thomas's Hospital, £9,000 to the Royal Northern Hospital, £8,000 to King's College Hospital, £7,500 each to the Middlesex Hospital and Westminster Hospital, £7,000 to University College Hospital, £6,900 to St. George's Hospital, £6,050 to the Prince of Wales's General Hospital, £6,000 each to St. Mary's Hospital and the Royal Free Hospital, £5,700 to Queen Mary's Hospital for the East End, £5,000 each to the Hospital for Sick Children and the West London Hospital, £4,750 to the Queen's Hospital for Children, £4,500 each to Charing Cross Hospital and the Royal National Orthopaedic Hospital, £3,700 to the National Hospital for the Paralysed and Epileptic, £3,600 to the Miller Hospital, £3,550 each to the City of London Hospital, Victoria Park, and the Dreadnought Hospital, and £3,500 to the Metropolitan Hospital.

Sir COOPER PERRY then presented the report of the Distribution Committee with reference to convalescent homes not attached to particular hospitals. This showed that £2,000 had been distributed during the year. Major WERNHER (honorary secretary) presented the schedule of awards.

### *Growth of the King's Fund.*

The PRINCE OF WALES said that the King's Fund was to-day taking another stride forward, the distribution being increased by £15,000. The increase in income, which had more than balanced a fall in legacies, was chiefly due to the dividends from the bequests of Lord Mount Stephen and Sir Thomas Sutherland, together with an anonymous donation of £6,500. Gifts to the King's Fund benefited nearly 150 institutions in proportion to their respective claims, as judged by the Distribution Committee, which had acquired a great amount of knowledge and experience. The novel feature in the report of the Distribution Committee was the new method of dealing with the recovery and convalescent branches of hospitals by amalgamating the grants to the branches with the hospital grants. The question of recovery branches had come up for decision this year because of the inquiry by the Hospital Economy Committee, whose report was before the Council. The Committee had made a thorough inquiry and considered that recovery branches were good, but that the hospitals and also the King's Fund must first count the cost, as in the case of any other form of hospital extension. There had been an interesting development of the work of the Revenue Committee. One subcommittee, under the chairmanship of Lord Burnham, had been appointed to assist; partly by general propaganda in aid of the work of the King's Fund and the hospitals; partly by enlisting the help of members of the professions of science, art, literature, law, etc.; and partly by continuing from time to time some of the activities of the Educational Auxiliary which had done such good work for the Combined Appeal. Another subcommittee would assist both the King's Fund and the hospitals to increase their revenue in any other ways not already covered by some existing agency. Lord Burnham's Committee was at present organizing another scientific novelties exhibition at King's College, and another set of lectures and counter-lectures at the London School of Economics in the spring. On the side of definite propaganda it had already issued a leaflet about the present financial position of the hospitals of London, and it would arrange for lectures in schools and elsewhere so as to inculcate in the mind of the public generally a greater sense of responsibility for the regular and systematic support of the hospitals.

Lord ULLSWATER, in moving a hearty vote of thanks to the Prince of Wales for presiding, alluded to the great care which His Royal Highness took to inform himself upon all the business of the Fund. The motion was carried with acclamation.

I were the founders of the society. I may add that this is the view he always held and referred to from time to time in conversation.

It is true that the project had the cordial support of the late Dr. George Carpenter from the beginning, but he did not assume the responsibility of taking the first public steps. He rendered yeoman service, and was editor of the excellent reports. He held at one time, like Mr. Stephenson and I, the office of Chairman of the Council, provide for a president.

I trust your readers will pardon the intrusion of the personal note, but, as the survivor of the three who are referred to, I feel sure that they who have left us would wish all the facts to be known.—I am, etc.,

A. H. TUBBY.

London, W., Dec. 22nd.

## Obituary.

SIR J. WALTON BROWNE, M.D., F.R.C.S., F.R.C.P.

Consulting Surgeon, Royal Victoria Hospital, Belfast.

It was with very deep and widespread regret that the intimation of the death of Sir J. Walton Browne was received by the profession in Ulster, and by a very large portion of the community. He had been in good health till some six weeks ago, when signs of heart failure manifested themselves, and he died quietly in his sleep on the morning of December 18th.

John Walton Browne was born in 1845, and was the son of Dr. Samuel Browne, R.N., J.P., who, when he left the navy, practised as an ophthalmic surgeon in Belfast, and became mayor of the town in 1870. His son Walton became a student of the old Queen's College, Belfast, and obtained the B.C. degree, and subsequently the M.D. He studied in Dublin, London, and Vienna, and when he returned to Belfast was soon appointed surgeon to the old Royal Hospital (now the Royal Victoria Hospital), and also to the Ophthalmic Hospital; the former post he held for thirty-seven years, and was appointed consulting surgeon a little over ten years ago; the latter he still held at his death. He was a member of many societies, and was president of the Ulster Branch of the British Medical Association, of the Ophthalmic Section of the Association in 1907, when it visited Belfast, and of the Ulster Medical Society. Sir Walton had been a senator in the old Royal University of Ireland, and on its dissolution he received the honorary degree of LL.D., and became a senator in the Queen's University of Belfast.

Well equipped him in his capacity for friendship; he was exceedingly popular, and his name became a household word throughout the North of Ireland. Although an active man devoted to hospital and surgical practice, he had a retentive memory and a wonderful knack of recalling articles in various medical journals dealing with any obscure point under discussion. His experience was wide, and he would quote case after case in support of the position he assumed in debate. All rejoiced when he was appointed deputy-lieutenant for the city with which he had been connected all his life; and there was a chorus of satisfaction on his receiving the dignity of knighthood from His Majesty when he opened the Parliament of Northern Ireland.

Sir Walton was twice married: he survived both his wives and also his son, but he is survived by his daughter, Samuel Brown, and a sister, live in England. Much sympathy is felt for these relatives.

SIR LAMBERT HEPENSTAL ORMSBY, M.D., F.R.C.S.I.

Senior Surgeon, Meath Hospital, Dublin.

We regret to announce that Sir Lambert Ormsby died at his residence in Dublin on December 21st. He had been in failing health for some time, but, notwithstanding this, had been out of doors as recently as a week before his death.

Lambert Hepenstal Ormsby was born at Onemunga Lodge, Auckland, New Zealand, in 1849, the only son of Mr.

George Owen Ormsby, C.B., his mother was a daughter of the Rev. Lambert Hepenstal, of Altadon, Delany, co. Wicklow. In his boyhood it was his ambition to enter the Royal Navy. Indeed, after an early education at the Commercial School, Auckland, the Lyceum, and the Grammar School, he left Auckland for London in 1864 with that end in view, but instead he went to the Royal School, Dunsannon. He studied medicine, was apprenticed to Mr. George Porter, later Sir George Porter, Bt., and at the age of 19 was a surgeon and physician. He had put in three years as a student at the Royal College and the Meath Hospital, where he was resident surgical pupil. He began to read for the Army Medical Service in 1868, but at this stage an accident determined his career. In a casual conversation with the late Dr. John Morgan, professor of anatomy in the Royal College of Surgeons, he was offered the position of anatomical demonstrator at that institution, and, accepting it, in two years became a skilled practical teacher. In 1872 he became surgeon to the Meath Hospital.

He entered Trinity College, Dublin, and graduated in arts in 1875; in the same year he became a Fellow of the Royal College of Surgeons, and in 1879 took the degree of M.D. Especially interested from an early period of his career in orthopaedic surgery and in the diseases of children requiring surgical treatment, he published two important volumes, the result of much study and practical experience, on *Deformities of the Limb and Body* and on the *Diseases Peculiar to Children*. In 1876 he founded the National Orthopaedic and Children's Hospital (now the National Children's Hospital), a humane and much needed enterprise, with the energetic promotion of which his memory will always be associated. This was by no means the only philanthropic movement which Surgeon Ormsby acted as chairman of the Association for the Housing of the Very Poor in Dublin, and the occasions were many upon which his broad-minded sympathies found practical expression.

From the year 1880 until his death Sir Lambert Ormsby devoted himself exclusively to surgical practice. He founded in 1885 the Dublin Red Cross Nursing Sisters' Home and Training School for Nurses, and watched over its development with assiduous care. He acted as senior surgeon to the National Children's Hospital, consulting surgeon to the Drummond Military School, Chapelizod, and honorary consulting surgeon to the Dublin branch of the Institute of Journalists. He was besides a member of the Board of Superintendence of Dublin Hospitals and governor of the Lock Government Hospital. He was a Fellow of the Royal Academy of Medicine, Ireland, and a Fellow of the Royal Medical-Chirurgical Society of London. From 1902 to 1904 he was President of the Royal College of Surgeons, Ireland, and it was during that term—in 1903—that the honor of knighthood was conferred upon him.

Sir Lambert Ormsby was twice married, and had four children (two sons and two daughters) by his first wife. His second wife was Geraldine Matthews, R.R.C., O.B.E., whom he married in 1921.

G. P. CHAPPEL, M.D., CANTAB., Physician, Meath Hospital, late Physician, Prince of Wales's Hospital, Tottenham.

We regret to record the death at Altincham, Cheshire, on December 15th, from pneumonia, of Dr. G. P. Chappel, who during the past five years had held the appointments of physician to the Altincham General Hospital and medical officer of health for Bowdon.

George Pester Chappel was born in 1868 at Camboorne, Cornwall, of which his father, the late Canon Chappel, was rector. From Marlborough he went to Caius College, Cambridge, and thence to the London Hospital. He graduated M.B., B.Ch., Cantab., in 1892, and proceeded M.D. in 1896. At the London Hospital he served as house-physician, and afterwards as house-surgeon to the late Sir Frederick Treves; his next post was that of resident medical officer to Victoria Park. Thenceforward, and until the war, he was engaged in general and consulting practice at Tottenham.

SATURDAY, DECEMBER 29TH, 1923.

## THE DEFINITION OF DRUNKENNESS.

THE problem of how best to deal with a drunken man has been with us ever since Noah's unfortunate lapse, but the development of motor transport has raised special difficulties which directly affect medical men. Everyone agrees that the drunken motor driver constitutes an unnecessary danger which calls for drastic suppression, and magistrates are tending to deal with such cases more and more severely. But the severer the punishment becomes for being drunk while in charge of a car, the more necessary is it to have a clear definition of what constitutes drunkenness, and the civil law expects medical men to be ready to give an opinion in such cases. Unfortunately there can never be any clear scientific definition of drunkenness. It is easy to say whether or not a man is under the influence of alcohol, and it is even possible by means of skilful tests for an experienced observer to define fairly clearly several stages of alcoholic intoxication; but the crucial question as to whether a man's brain is so clouded that he is unfit to be in charge of a car is one which must be decided by common sense, and scientific tests can give very little help.

The popular idea seems to be that a person taking alcohol retains his normal senses up to a certain point and then suddenly becomes drunk. This is, of course, erroneous, for even small doses of alcohol can be shown by accurate psychological tests to produce a distinct depression of the finer powers of judgement, although the subject in this stage appears to a casual observer to be completely normal. The popular opinion is, however, so far justified that sudden changes in behaviour are frequently seen in intoxicated persons, due to the fact that the inhibitory centres, which have been holding the disordered brain to a more or less normal course of action, lose control, and when this happens the effects of the gradual process of intoxication suddenly become apparent.

Alcohol intoxication, it is true, produces a descending paralysis of the brain, depressing first the higher and later the lower centres, but the grading of the different stages of intoxication is a matter of extreme difficulty, because the different functions of the brain are attacked in different order in different individuals, and even in the same individual the apparent effects of drunkenness vary greatly according to the surroundings. A man who will in convivial surroundings become hilariously drunk may, with the same dose of alcohol in quiet surroundings, merely go to sleep. Moreover, the rate at which skilled movements are affected by alcohol depends very largely upon the degree of practice the subject has in these movements, and also upon how accustomed he is to perform them when under the influence of alcohol. For example, a skilled musician who is also a chronic drunkard may be able to play with considerable skill when he is too drunk to stand. Consequently it is very difficult to devise a fair test for drunkenness based on the performance of skilled movements, because the test depends so largely on the degree of practice the individual has in the subject of the test. For example,

a writing test is much more severe for a manual worker than for a clerk.

The problem has reached an acute stage in Denmark, for under the Danish law a man may be permanently deprived of a licence to drive on a single conviction of being drunk while in charge of a car. Hence a uniform standard for tests for drunkenness has become an urgent necessity. At the request of the Chief of the Police the Danish Medico-Legal Council, in consultation with a pharmacologist and an alienist, worked out a scheme for clinical examination to be followed by all medical practitioners examining cases of drunkenness. This scheme, of which a brief account was given in the *BRITISH MEDICAL JOURNAL* of September 15th, 1923 (p. 487), is on the usual lines. It requires the practitioner to observe the general condition of the subject, the presence or absence of smell of alcohol, and the condition of speech, gait, handwriting, and pulse; it prescribes also a simple memory test. A medical expert was appointed whose services were immediately available in Copenhagen by day or by night to examine motor drivers accused of drunkenness. This expert has made a report on the results of the examination of fifty cases. Perhaps the most significant point is that he spent on an average forty-five minutes in the examination of each case, and considered that such a length of examination is essential to arrive at a just conclusion in doubtful cases. He found that the pulse rate gave little help, and that pronunciation and handwriting tests were of little value on account of the low standard of education of most of the persons examined. Memory tests were, however, of great value, and one of the most useful was to demand from the subject a short coherent account of some recent event.

The expert's notes are of interest, since they suggest that the time required for examination for drunkenness is considerably longer than is usually thought necessary, and also that the tests in general use in this country might be considerably improved. While an expert regularly engaged in examining cases of suspected drunkenness may become able to fix a fairly uniform standard of what constitutes drunkenness, the problem still remains as to how he can transmit this knowledge to others. In principle there is an analogy between the position of the medical witness in these cases and that in which he is placed in the High Court when the issue is whether the accused is to be held responsible for the crime with which he is charged. The High Court has all the facts before it. In charges of drunkenness against a motor driver the police know all the circumstances and may be aware that in a particular instance a trained driver has driven in a grossly incompetent way. The police call in the doctor to confirm their impressions and conclusions, and while in extreme cases he may have little difficulty, there are, as we have shown, many intermediate stages where a definite decision may be extremely difficult. It seems doubtful whether a fixed schedule for clinical examination will be of any great practical value. The appointment of an expert to examine all cases in an area certainly seems a step towards obtaining uniformity in administration of the law, and if such experts occasionally worked in couples it would be possible to ensure that a fairly uniform standard was maintained.

Any steps in this direction would probably be welcomed by the medical profession, for the giving of evidence in cases of drunkenness is a difficult and unsatisfactory task for medical men who have not any special experience in the examination of such cases.

becoming physician to the Prince of Wales's General Hospital and a member of the teaching staff of the North-East London Post-Graduate College. In those days Chappel was an enthusiastic member of R.A.M.C.(T.F.), and subsequently, on relinquishing his commission after the war, he was awarded the Territorial Decoration. He was mobilised in 1915 and served in France and Belgium for three years, for thirty-three years.

Dr. Chappel had been a member of the British Medical Association for nearly thirty years, and at the time of his death was a member of the Executive Committee of the Mid-Cheshire Division.

THE LATE MR. SYDNEY STEPHENSON.

Mr. A. H. TERRY, C.B., C.A.I.G., M.S., writes: As one of his intimate friends, I would like to refer to some of Mr. Sydney Stephenson's colleagues for many years, and

"One who never turned his back, but marched breast forward  
Held, we fall to rise, are balled to fight better,

Dr. ARTHUR MITCHELL, medical superintendent of the County Mental Hospital, Hutton, Warwick, died on December 4th, 1901. He was educated at Trinity College, Dublin, and graduated M.B., B.Ch.Dip. in 1881. He had been connected with the asylum for about forty years, first as assistant medical officer and for thirty-four years as medical superintendent. He was also medical adviser of the County Mental Deficiency Committee, registrar of the Medical-Psychological Association of Great Britain and Ireland, and a member of the committee of management and house committee of the Warneford Hospital, Leamington. He was a keen sportsman, and in his early life was an Irish international Rugby footballer. He is survived by his widow and two daughters.

We regret to record the death of Dr. WILLIAM THOMAS MADDOCK, which occurred very suddenly in the early morning of December 9th at Stapleton Road, Bristol, where he carried on a large practice for over twenty years. He was educated at King's College, London, of which he was a senior scholar and afterwards an Associate. Having obtained the M.R.C.S. diploma in 1881 he became house-physician to King's College Hospital and graduated M.B. (physician honours) in the following year, proceeding M.D. in 1886. After a period as assistant medical officer to the Metropolitan District Asylum at Darenth, Dr. Maddock

By the untimely death, in his 49th year, of Dr. ROBERT WALKLEY FISHER, Director of the Public Health Department of Bombay has lost one of its most devoted workers. Dr. Fisher was born at Ballymena, County Antrim, Ireland, on November 10th, 1874, and graduated M.B., B.Ch. in 1901 at the Royal University of Ireland. After holding the appointments of resident medical officer of fever and small-pox hospitals at Belfast, and a short experience of general practice, he undertook plague work in the Punjab for about four years from 1902 to 1903 and again from 1904 to 1908. After his return to Ireland he took the D.P.H. (R.U.I.) in 1909. His plague work in the Punjab had attracted such favourable attention that it was felt that the services of such an enthusiastic worker should be permanently secured. In 1911 the Secretary of State sanctioned the creation of an appointment of Director of Vaccine Institute, and on the recommendation of the Government of India, offered it to Dr. Fisher, who took charge of the Vaccine Institute, Belgium, in August, 1911. The vaccine lymph manufactured at Belgium was successfully used throughout the year in Sind—the hottest part of India—and during the great war he supplied the Bombay army and several overseas forces with a reliable vaccine lymph. In addition to his duties he acted also as civil surgeon, Belgium, and as deputy sanitary commissioner, S.R.D., for a short time. In 1921 he graduated M.D. (R.U.I.), and his thesis, which had as its subject the history and work of the Vaccine Institute, Belgium, was deemed worthy of a gold medal; this thesis was published in the *Indian Journal of Medical Research* (vol. 8, No. 2, October, 1920). In 1923 he was awarded the Kaiser-i-Hind medal in recognition of his multifarious services and fine work in connexion with the Vaccine Institute, Belgium. He was genuinely admired by all for his ability and for his generous disposition; he was ever ready to spend himself in the interests of others. The funeral took place on October 26th at the Belgium cemetery in the presence of a large number of friends. Dr. Fisher leaves a widow, two sons, and a daughter; the elder son has just entered as a medical student at the Royal University of Ireland.

Dr. Frederick CORIN BENZIE, who died on October 18th, 1913, was educated at Victoria University, Manchester, where he took the degree of M.B., Ch.B. in 1913. He held the rank of captain in the Royal Army Medical Corps, Territorial Force, and saw active service abroad both in France and Gallipoli. He had filled the appointments of district medical officer and public vaccinator in Manchester, assistant medical officer at Baginbun Sanatorium, house-physician and house-surgeon at the Manchester Royal Infirmary, and medical officer in charge of the New Bridge Street Hospital in Manchester. Captain F. Anot Baum, R.A.M.C.(T.), writes: "I was at the Grammar School with him twenty years ago, and he showed the same quick, sensitive nature and versatility which he developed to a greater degree later in life. I well remember the caricatures he drew, and the parodies he wrote, during the election of 1906. He was an omnivorous reader, had a fine taste for English literature, and an undoubted flair for the classics. He was in my year at Manchester University, and was on 'the house' together. He was the life and soul of any party; no 'last night' was complete unless he gave one of his inimitable burlesques, either of a colleague or one of the staff; and it was characteristic of him that no one enjoyed his burlesques better than the man who was the original of them. When war broke out he was one of the first to volunteer, and I was not surprised to hear of his struggling back to the trenches in France before his terrible wounds had really healed." A brother officer in the 42nd Division Field Ambulance bears witness to the unflinching and exuberant high spirits and power of extracting humour from the grimmest and most unpromising

number of notifications and the number of deaths from pulmonary tuberculosis is of interest as indicating the variations which exist in this matter. From many talks with doctors and students I am satisfied that the sound line of approach is by the way of awakened interest, *esprit de corps*, and, if you will, patriotism.—I am, etc.,

University of Edinburgh, July 8th.

R. W. PHILIP.

SIR,—In the *BRITISH MEDICAL JOURNAL* of July 7th (p. 43) there is published an interesting letter from the Deputy Clerk to the London County Council headed "Earlier notification of tuberculosis."

I do not think many of those who have to do specially with tuberculosis would declare it as their belief that the failure on the part of medical practitioners to notify cases earlier is due to "wilful neglect or refusal to carry out the Tuberculosis Regulations" of the Public Health Act. It would have been, indeed, surprising if the conference between the Public Health Committee of the London County Council and representatives of the metropolitan borough councils had come to the conclusion "that prosecutions would be the most hopeful means for increasing the proportion of early notifications."

The earlier notification of tuberculosis is dependent on earlier diagnosis, which again is dependent on the skill of the medical practitioner. A practitioner cannot yet be prosecuted for lack of skill in diagnosis, or which of us would escape prosecution at some time or other in the course of our professional careers?

The real clue to the problem—how to obtain earlier diagnosis and therefore earlier notification—is mainly to be found in the final clause of the Deputy Clerk's letter, which appears as a sort of "addendum" or afterthought. He was instructed—he tells us—to invite the London Panel Committee and the British Medical Association "to direct the attention of their members to the fact that the services of the tuberculosis officers are available for consultation, etc."

In the county area in which I myself work as tuberculosis officer it is unquestionably the fact that a majority of patients, by the time they come under official notice, are already in an advanced—or, at least, not an early—stage of the disease. This, of course, does not necessarily imply that the medical practitioner has failed to diagnose the case earlier. It may simply be that the patient has put off going to his doctor month after month, until, when at last he goes, the disease has become already firmly established. Still there are undoubtedly many cases where patients attend their doctor for several weeks or even months for vague symptoms of "bronchitis," "catarrh," "colds," etc., who eventually prove to be cases of pulmonary tuberculosis; and if only all such cases were referred at an early period to the tuberculosis officer for examination, or a consultation with the tuberculosis officer were invited, a distinct rise in the number of cases diagnosed "early" would result. As the Chief Medical Officer of the Ministry of Health says in his annual report (1920, p. 85):

"The medical practitioner should, therefore, not hesitate to refer for the advice of the tuberculosis officer not only those cases in which indubitable signs of tuberculosis are already present, but also those patients who show any symptoms which may suggest the slightest possibility of early tuberculosis. A practitioner fails in his duty to his patient if he continues to treat for long periods cases of debility or those suffering from bronchitis or recurring colds or pleuritis without having the most searching examination made to exclude tuberculosis."

Unfortunately not all Local Medical and Panel Committees view with favour the tuberculosis organization which is now general throughout the several counties and county boroughs. For instance, the Local Medical and Panel Committee for Cheshire has declared its opposition to the whole tuberculosis scheme, and would like to see tuberculosis dispensaries and tuberculosis officers abolished. In this case there is reason to doubt that the Committee really represents the attitude of the bulk of medical practitioners, but the spirit of hostility is none the less deplorable. The Departmental Committee on Tuberculosis stated at the very beginning of the consideration of anti-tuberculosis schemes, "It is of primary importance to the

lasting success of any scheme dealing with tuberculosis that it should enlist the hearty co-operation and stimulate the interest of the general medical practitioners of the country." If this co-operation is lacking, the success of any anti-tuberculosis organization on public health lines can never be assured under present conditions of medical practice, and failure to secure early diagnosis of the disease will continue to be one of the stumbling-blocks in the way of dealing successfully with tuberculosis.—I am, etc.,

E. WEATHERHEAD,  
June 8th. Tuberculosis Officer, North-East District, Cheshire

### "DIAPLYTE" VACCINES AND ANTIGENS.

SIR,—In view of the striking application by Professor Dreyer of the formaldehyde-acetone method of defatting or diaplyting the tubercle bacillus, it may be of interest to workers in this field to record the following observations in regard to the preparation of red blood cells for phagocytosis by human leucocytes.

If one drop of a suspension of the red blood cells of the sheep, thoroughly washed in normal saline, be incubated in a closed cell with two or three drops of human (C.J.B.) blood, an inhibitory or toxic influence is exercised by the washed sheep's red cells on the human leucocytes. Very few leucocytes emigrate from the clot or adhere to the slide, and the few cells which do emigrate show marked signs of cytolytic change. This effect is true of the red cells of individual sheep only, and after testing the red cells of over 100 sheep I find that about 70 per cent. are toxic and about 30 per cent. non-toxic to my own leucocytes. In the latter group free emigration of leucocytes takes place on incubation, many leucocytes show sheep's red cells adherent to them, and many contain ingested sheep's red cells.

If now the washed red cells from the blood of a sheep which is known to be toxic to human leucocytes be first treated with a 1 per cent. solution of formaldehyde in normal saline, centrifuged, washed, and then treated with a 5 per cent. solution of acetone in normal saline (to the verge of haemolysis) and again rewashed and incubated with human (C.J.B.) blood, the sheep's red cells, as the result of the treatment by formaldehyde and acetone, will have lost their toxicity. Free emigration and ingestion of the sheep's red cells by the human leucocytes will take place.

If, however, the rewashed red cells so treated be resuspended and reincubated in their native sheep's blood serum, then, on rewashing and reincubation they will be found to have regained their original toxicity.

Thus, whatever be the exact nature of the material which gives the sheep's red cell its toxic influence, it is probably derived in some way from the sheep's blood serum, which is in itself very toxic to human leucocytes.

But this detoxication of sheep's red cells (by formaldehyde and acetone) can also be obtained by treating the washed red cells by certain human blood serums. The red cells are immersed and preferably incubated for an hour or more in the blood serum of an individual previously known to exercise an opsonic effect on sheep's red cells. The suspension is then centrifuged, the cells are well washed in normal saline solution, and when incubated with the same (C.J.B.) blood are found to be non-toxic.

The fact suggests that the toxic coating on the sheep's red cells can be removed, or its toxic nature reversed, by immersion in human serum of an opsonic character. It is possible that the immunity of normal red cells to attack by their own leucocytes, while circulating in the blood, may depend on a delicate interaction between the red cells and the blood plasma in which they are suspended.

There is also some evidence that while the detoxicating effect exercised by an opsonic serum on toxic red cells is often associated with an agglutinating action on the same cells, yet the two effects are not entirely dependent the one on the other. Thus both agglutinating and non-agglutinating serums may opsonize the same red cells.

A further study of the detoxicating and opsonic effects of different chemical substances, and of different blood serums, on the red blood cells of the sheep and other animals, and also on the red cells of human individuals under different conditions, is bound to throw additional light on the means

situations which made Captain Bentz a real inspiration during the months spent at Cape Helles: "He could always dispel the gloom of his brother officers by some whimsical imitation of a former teacher or an extravagantly witty burlesque, and his popularity amongst the rank and file was unbounded. When he received the severe chest wound which laid the foundation of prolonged ill health, and eight years later was the cause of his death, there were general expressions of grief and consternation, and the stimulus of his cheerfulness was deeply missed after his departure." His partner, Dr. Wolfendale, bears similar witness to Dr. Bentz's bright and cheerful disposition, which endeared him to the hearts of the people with whom he came in contact. Dr. Bentz married Miss Roberta Thompson, who, with an infant son, survives him.

Dr. ROBERT IRVINE GARDNER of Enfield died recently in a nursing home following an operation for an internal malady, aged 58. He was the son of Mr. James Gardner of Glasgow, and graduated M.B., C.M.Glas. in 1886. When he first went to Enfield he was assistant to the late Dr. Collyer, whom he succeeded in 1896 as medical officer of the Chaso Farm schools. Dr. Gardner was also medical officer and public vaccinator for the Enfield district and workhouse of the Edmonton Union, and was a member of the North Middlesex Division of the British Medical Association. He is survived by his widow and young son.

Dr. THOMAS PATTERSON DEVLIN, of Balfour, British Columbia, died at Westminster, British Columbia, on October 30th. He was educated at Queen's College, Belfast, and took the L.R.C.P. and S.E.din. in 1882. Afterwards he went into practice at Great Yarmouth, and while resident there he joined the 1st Norfolk Volunteer Artillery, in which he held the rank of captain from November 22nd, 1899; later he held the same rank in the R.F.A.(T.F.). Five years before the war he went to Canada, where he took the diploma of L.C.P.S. British Columbia in 1909. He joined the army for the late war as a temporary lieutenant R.A.M.C. on February 10th, 1915, became captain after a year's service, and later was promoted to major. When demobilized in 1920 he returned to Canada.

Dr. DELCROIX DE COSTER, President of the Belgian Urological Society, has recently died.

Professor ALEXANDER ELLINGER, a well known German pharmacologist and dean of the medical faculty of Frankfurt since its establishment in 1914, has recently died at the age of 53.

## Universities and Colleges.

### UNIVERSITY OF CAMBRIDGE.

At a congregation held on December 19th the following medical degrees were conferred:

M.D.—A. W. Uloth, E. H. R. Altounyan, E. Wordley.

M.B., B.Ch.—E. Tagoo.

M.B.—R. N. P. Wilson, G. H. Caiger, C. Dunscombe.

The following candidates have been approved at the examination indicated:

THIRD M.B., B.Ch.—Part I:

E. V. Beale, F. M. Coll, Craib, G. J. V. Crosby, E. J. H. Doggart, R. B. Fawkes, W. H. Gervie, R. A. Highmoor, J. W. Hope Simpson, R. Jackson, J. P. W. Jamie, W. A. Lister, H. R. Matthews, G. A. Metcalfe, H. D. N. Miller, S. M. Milner, E. G. Morris, J. Ness-Walker, C. E. Newman, G. G. Penman, A. D. Porter, E. A. B. Pritchard, R. H. T. Ren, R. L. Rhodes, W. L. Roberts, R. A. M. Scott, W. G. Scott Brown, F. A. H. Simmonds, L. V. Snowman, G. L. Thompson, G. K. Thornton, R. W. Thorp, F. G. O. Valentine, S. Vatcher, A. L. Walker, R. K. Wilson, F. B. Winton, H. Yates. Part II—Principles and Practice of Physic, Pathology, and Pharmacology: J. C. Ainsworth-Davis, L. J. Bendit, N. E. Chadwick, W. H. Craib, F. E. Graham-Hopkiss, G. T. Henderson, E. G. Holmes, J. W. Hope Simpson, R. Jackson, L. P. Lockhart, E. A. Linton, R. J. Lythgoe, T. K. MacLachlan, F. H. Mather, G. A. Metcalfe, G. C. Millis, E. S. Page, R. J. V. Pulverstat, B. E. Schlusinger, M. H. Webb-Peploe, R. H. White, R. K. Wilson; also G. M. Brown Girtou.

### UNIVERSITY OF LONDON.

Miss ELEANOR M. SCARBOROUGH, M.B., B.S., B.Sc.Lond., has been appointed as from January 1st, 1924, to the recently instituted Readership in Pharmacology tenable at the London School of Medicine for Women.

Professor Hugh MacLean, D.Sc., M.D., Ch.B., has been awarded the William Julius Mickie Fellowship (of the value of £200) for 1924 in respect of the work which he has carried out during the past five years in experimental medicine. This Fellowship is awarded annually, under the terms of the Mickie Bequest, to the man or woman who, being resident in London and a graduate of the University, has done most to advance medical art or science within the preceding five years.

The following candidates have been approved at the examination indicated:

M. . . . . J. V. C. Braithwaite, R. T. Lewis, M. Addimore, M. J. Panthaky. BRANCH III  
Mary R. Barkas. BRANCH IV (Midwifery)  
Sybil G. Mocatta. BRANCH VI (Tropical)

M. . . . . J. McCurrich, A. C. Perry.  
\* University Medal.

### UNIVERSITY OF LEEDS.

THE following candidates have been approved at the examinations indicated:

M.D.—H. Caplan, R. E. Jowett, A. Sheard.

FINAL M.B., Ch.B.—Part I: D. R. Allison, M. Backwell, Sara N. S. Barker, Rosie B. Becker, Kathleen Roddy, T. H. Carr, J. Cohen, R. Cohen, F. R. Curtis, J. S. Dinadale, J. Duncan, J. Ewing, G. K. Fitton, W. S. Flowers, Elsie G. M. Ford, G. Gorstige, J. R. S. Greenwood, P. V. Hardwick, J. L. Hartley, A. Hemingway, W. R. Hill, W. O. S. Hornby, S. Leviten, G. M. D. Lobban, A. V. McLean, M. Masser, J. L. Moorhouse, W. Murphy, S. Nagley, J. H. O'Donnell, Edith V. Oliver, R. S. Pyrah, M. Rabinovich, Rosamond E. Roper, J. W. Silversides, S. K. Sledge, Ann Sugden, G. W. Taylor, R. W. L. Ward, A. C. Welch, D. Zimmerman. Part II: C. H. Actroay, J. Cardis, G. Chambers, A. Franklin, G. D. Gordon, Muriel D. Graham, E. L. H. Jones, I. Kovelman, A. H. Morley, J. W. Pickard, Kathleen M. Potter, N. A. Scadding, K. A. Turner. Part III: \*R. Chester, \*F. N. Foster, \*E. Holmes, \*Gretta M. Wardle, Marjorie Baxter, D. Brabant, R. E. Crockett, J. Freeman, Marjorie M. Jackson, R. H. Lodge, R. Marinkovitch, H. M. Petty, H. Sheard, J. S. Walker, N. F. Windsor.

D.P.H.—Ella G. Bolton, Mabel M. Maclean, M. J. O'Neill, Jessie Sheard.

The William Hey Medal for 1923 was awarded to G. F. Walker, who obtained the M.B., Ch.B. degree with first class honours in June, 1923.

The West Riding Panel Practitioners' Prize in Medicine was awarded to Myer Cohen, who obtained the M.B., Ch.B. degree with second class honours in June, 1923.

\* With second class honours.

### VICTORIA UNIVERSITY OF MANCHESTER.

THE following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B. (New Regulations).—C. N. Aldred, W. Broadhurst, J. F. Bromley, Hestia E. Cook, \*R. W. Fairbrother, Madge K. Heywood, Bertha Kahn, L. W. Kay, A. C. Kelly, V. F. Lambert, W. B. McKelvie, Marjorie Robinson, Kate B. Thompson, Sarah Obsterics and Surg. W. C. V. Brothwood, T. A. I. Davies, R. Ellis, L. Fay, C. R. Fielding, A. G. Forbes, Anna H. Ghaney, J. W. Graham, P. Gregory, E. Holmes, Winifred L. Horton, J. N. Hudson, Phyllis Kaufmann, D. Kemp, Hilda M. Linford, F. R. Lockhart, S. Bopo, L. J. Prosser, A. Riley, Eileen Sheehan, Dorothy Simmons, J. Sims, G. S. Smith, A. R. Somerford, J. Troup, H. M. Turner, C. Willcocks, G. Williamson. Obsterics: J. H. Anderson, S. Bernstein, Madge E. Edwards, P. G. Johnston, Alice M. O'reill, R. F. Stubbs. Forensic Medicine: C. E. W. Bower, Gladys F. A. McLean. Hygiene and Preventive Medicine: C. E. W. Bower, C. Eccleston, Gladys F. A. McLean, W. M. Roberts, H. C. Smith, E. Whiteside.

\* Awarded distinction in Obstetrics.

### UNIVERSITY OF SHEFFIELD.

THE following candidates have been approved at the examination indicated:

FINAL M.B., Ch.B.—C. R. Bailey, L. H. Copping, T. R. Forsytho, C. H. Greaves, C. Myers, J. E. Tannian.

### ROYAL COLLEGE OF SURGEONS OF ENGLAND.

THE following are the successful candidates at the recent primary examination for the Fellowship of the Royal College of Surgeons of England; 144 candidates presented themselves, of whom 105 were rejected:

G. F. G. Batchelor, R. Broomhead, H. J. A. Colvin, E. H. Derrick, R. L. Dodds, P. Dooley, N. L. Edwards, W. S. D. Elder, D. C. M. Eddles, C. W. Flemming, H. L. H. Green, W. J. Henry, A. Hobson, B. R. Hosiard, F. J. Jauch, G. Macafee, G. F. H. McCormick, J. Mintzman, Marjorie Low, C. H. E. Macafee, A. L. to Water Naude, H. P. Ne'san, E. D. Moir, W. M. Muirhead, A. H. R. Pomroy, S. M. Power, M. M. Marion G. Palmer, R. T. Payne, H. R. Pomroy, S. M. Power, M. M. Riad, G. D. Robb, A. R. Rutnam, J. J. Savage, E. X. Scab, S. V. Unsworth, R. M. Walker, J. Whillis.

### ROYAL COLLEGE OF SURGEONS OF EDINBURGH.

THE following candidates, having passed the requisite examinations, have been admitted Fellows:

Albert Clifford Abbott, Thomas George Doughty Bonar, Hendrik Johannes Petrus Bruwer, Gerrard Burnett, Thomas Lindsay Clark, Robert Malcolm Duncann, Ernest Chalmers Farnay, Griffith John Hughes, William Ibbotson, Hubert Sydney Jacobs, Thomas Porter McMurray, James Herbert Rawlinson, Creusa Shepherd, Charles Hamblen Thomas, Henry Ellis Yeo White.

Sinnatambu Thambipillai has been admitted a Licentiate of the College.

definite period, to a committee appointed for the purpose. By this means valuable data should be obtainable from which to estimate the value of different techniques.

#### DISCUSSION.

Dr. McNAMARA said that the only criticism he would level against Dr. Moomings' paper was that an undue amount of time had been spent in discussing the miserable questions "who was to blame, and who was not to blame," the prevalence of these fatalities where chloroform was used even in the hands of the best experts, and considering also that where ether was used even by non-experts, as in America, there was almost no mortality due to the administration of anaesthetics, those were to blame who used, or allowed to be used, chloroform on their patients.

Dr. STURGEON (London) drew attention to the question of oral sepsis and the necessity of dealing with this by suitable antiseptic measures being taken before operation. He also pointed out that atropine was usually used in too small doses.

Dr. C. H. MORT (Burslem) asked whether the tight bandaging referred to concerned the chest or the abdomen. Tight bandaging was especially employed after breast cases, and in these cases might do harm by restricting the breathing. He mentioned also that in the taking of blood pressures different readings could be obtained by taking them (1) with the hand at the side, and (2) with the hand raised. Thus readings could only be compared when they were taken with the hand on each occasion in the same position relative to the axis of the trunk. Referring to students not being taught to give chloroform if the chloroformists had their way, he thought that this might be an advantage except possibly in the case of the professional anaesthetist.

### ANAESTHESIA BY THE GAS-OXYGEN-ETHANESAL AND THE GAS-OXYGEN-CHLOROFORM-ETHANESAL COMBINATIONS.

H. EDWARD G. BOYLE, O.B.E., M.R.C.S., L.R.C.P.,

Anaesthetist and Lecturer on Anaesthetics to St. Bartholomew's Hospital.

The aim of all anaesthetists should be so to produce and maintain anaesthesia as to give satisfaction to the operator, safety and a minimum of discomfort to the patient, and reward, and mayhap praise, for the anaesthetist. With these aims in view I have been endeavouring during the last six or seven years to perfect a method which would as far as possible fulfil the necessary requirements, and in the gas-oxygen-ethanesal and gas-oxygen-chloroform-ethanesal combinations I think that we have methods which, when properly employed, will give better results than the majority of us were wont to obtain by other means.

Now, anaesthesia by these combinations entails a little more than the mere giving of the anaesthetic, for, to obtain really good results, attention must be paid to medication prior to the actual administration. Thus I advise a hypodermic injection half an hour before the operation, and the contents of this injection vary with the patient and with the operation—for example, for children I usually order 1/200 grain of atropine to be given thirty minutes before the operation, for the older children, the patient and with the operation—for example, for atropine 1/150 grain, while for adults I prefer the "hyoscine compound A," of Burroughs and Wellcome, and for big strong men their "hyoscine compound B." I have tried a great many variations of these preliminary injections, and find that those I have mentioned give the best results. In regard to the contents of the "ether" bottle, experience has shown me that to obtain the best results

There is one evil which seems likely to arise out of the rather vigorous campaign which some authorities, with the best of intentions, are waging against chloroform—that is, that there is a chance that the rising generation of practitioners may be so unfamiliar with chloroform that they will be unable to use it with confidence or safety.

With your indulgence I should now like to revert to some of these points with the object of discussing with you the difficulties which seem to offer most hope of solution. The danger of syncope occurring during chloroform anaesthesia is now an established fact, and reports of cases leave no doubt that the chief contributory factors are (1) any interference with respiration, and (2) the use of too concentrated a vapour. The first of these may be very obvious and accompanied by cyanosis, as, for instance, when the obstruction to free entrance of air results from faulty position of the jaw or from muscular spasms. Fortunately this type of trouble is easily removed by introducing an airway or by traction on the jaw, but a much more insidious form of faintness may result from the accumulation of mucus or blood in the larynx, which is best got rid of by cough. This cause of faintness may easily be overlooked, and in not a few of the cases reported has ended fatally. In this connexion I am tempted to refer to what seems to me to be a misinterpretation of Goodman Levy's teaching concerning the safety of deep chloroform anaesthesia: in certain instances, when alarming symptoms have arisen, they have been considered an indication for deeper anaesthesia, with disastrous results; but it is certain that the indication is rather to get the airway clear before doing anything else.

We come across quite a number of instances where death has taken place shortly after the patient has been moved from one table to another, or from one position to another. With the excessive relaxation of profound anaesthesia any change of the patient's position may cause a fall in blood pressure, and, in high stages of narcosis, movement is apt to lead to vomiting with its usual faintness. The concentration of vapour depends largely upon the extent to which the airway is kept free from obstruction. I am sufficiently optimistic to believe that surgeons and anaesthetists, working together with the common object of trying to conserve as far as possible the blood pressure and muscular tone, will be able to lessen operation risks still further. That the importance of these two factors is now well appreciated in most quarters is shown by many of the letters I have received from anaesthetists personally interested in some of the cases recently reported.

For the sake of clearness I will avoid many words, and simply state what I believe to be the essential facts. When blood pressure falls seriously during manipulation, such as traction on the mesentery, it will generally return to normal, or nearly normal, when the manipulation stops, provided it has not been kept low for longer than fifteen or twenty minutes. It is of the utmost importance that the surgeon should help the anaesthetist as far as possible in this respect. The question of muscular relaxation is, to some extent, a matter of arrangement between surgeon and anaesthetist; too little is bad for the surgeon, but too much may be fatal for the patient. Relaxation of a group of muscles may conveniently be obtained by the injection of a local anæsthetic; this course enables the general tone to be maintained, which helps very materially to preserve the proper level of blood pressure. I have come across six or seven instances in which deep anaesthesia was associated with a dangerous slowing of the pulse rate—to between 30 and 40 beats a minute—whereas, in the same patient, the pulse rate remained normal as long as the corneal reflex was not abolished. I feel that in such cases one is justified in refusing to deepen the anaesthesia, and thus probably save one's patient though perhaps losing one's surgeon. When we come to consider the various causes of death after operations we find pneumonia and bronchitis too much in evidence. In conclusion, I would suggest that improvement in this direction would be enhanced if a large number of anaesthetists could be induced to send reports of any such cases they might meet with, during some

## The Services.

### D.M.S. INDIA.

MAJOR-GENERAL O. L. ROBINSON, C.B., C.M.G., Army Medical Service, has taken up the post of Director of Medical Services of the Army in India in succession to Major-General Bowle-Evans, Indian Medical Service, who recently vacated the appointment, which he has held only since July last.

### DEATHS IN THE SERVICES.

Colonel George Taylor Goggin, Army Medical Staff (retired), died at Folkestone on December 16th, aged 70. He was educated at Queen's College, Cork, and took the L.R.C.P. and S.Edin. in 1877. He entered the army as surgeon in 1880, attained the rank of colonel in 1907, and retired on January 14th, 1910. He served throughout the South African war, 1899 to 1902, and held the local and temporary rank of colonel. He took part in the relief of Ladysmith, including the actions at Colenso, Spion Kop, Vaal Krantz, Tugela Heights, and Pictet's Hill; operations in Natal, including the action at Laing's Nek; in the Transvaal, east of Pretoria; and in the Orange River Colony, where he was in charge of a general hospital. He was twice mentioned in dispatches, and received the Queen's medal with six clasps and the King's medal with two clasps. After his retirement he rejoined for service in the late war, when he was employed as D.D.M.S., Western Command, and later as A.D.M.S. at Devonport.

Lieut.-Colonel John Latchford, R.A.M.C. (retired), died at Falmouth on November 29th, aged 73. He was born on April 14th, 1855, and educated at Trinity College, Dublin, where he graduated A.B. in 1884 and M.B. in 1885. He entered the army as assistant surgeon on March 31st, 1883, served in the 1st Foot, the Royal Scots, under the old regimental system, became surgeon major on March 31st, 1890, and retired on March 27th, 1899. While on the retired list he was employed at Galway in 1896-1901, and in Dublin from 1902 to 1903.

Lieut.-Colonel Daniel Grove Marshall, Bengal Medical Service (retired), died in Edinburgh on December 16th. He was born on September 4th, 1850, the son of Robert Marshall of Shrewsbury, and educated at Edinburgh University, where he graduated M.B. and C.M. in 1885. After filling the post of house-surgeon of the clinical wards in the Edinburgh Royal Infirmary, he entered the I.M.S. as surgeon on March 31st, 1888, passing first both into and out of Netley, where he took the Herbert prize, the Parkes Memorial medal in hygiene, and the Montefiore prize and medal for surgery. He became major on March 31st, 1900, but was placed on temporary half-pay on account of ill health in 1904, and had to retire, for the same reason, in the following year. He settled in Edinburgh, where he became lecturer on tropical diseases in the Extramural Medical School in 1905 and in the University in 1909. He served in the Burmese war in 1893-92, receiving the medal with a clasp; on the North-West Frontier in the Isazai campaign of 1892, and in the Tchi in 1897-93 (medal with clasp); and in the China war of 1900, including the relief of Peking (medal with clasp). In October, 1918, he was appointed a temporary lieutenant-colonel in the R.A.M.C. and was consultant on malaria for the Scottish Command, and received an honorary step of promotion to lieutenant-colonel from October 15th, 1919.

## Medical News.

NEGOTIATIONS have recently been conducted between the Danish Medical Association and the Danish Government with regard to the former's request that doctors' motor cars should show a distinctive sign indicative of certain privileges, such as the right to leave a car outside a patient's house, to use roads not intended for ordinary motor traffic, and to exceed the ordinary speed limit. The authorities have not granted all that was asked, but it has been intimated to the Danish Medical Association that the police will be given instructions to allow some at least of the latitude desired for the medical use of motor cars. This concession is the more welcome as it has long been felt to be a grievance that the doctor who leaves his car in a street to attend to a case of difficult labour has been as liable to prosecution as the lady who spends an hour receiving manicure attention while her car waits in the street.

A COURSE of free lectures on cancer will be given by members of the staff at the Cancer Hospital, Fulham Road, Kensington, to medical practitioners, on Wednesdays at 4.30 p.m., commencing January 2nd, 1924, and concluding on March 19th. The lectures will deal with every aspect of the subject, and an endeavour will be made to present the developments of research in etiology, diagnosis, and treatment.

THE fourth annual dinner and dance of the Panel Committee for the County of London will be held at the Wharfedale Rooms, Hotel Great Central, Marylebone Road, Road, N.W.1, on Thursday, January 3rd, 1924, at 7 p.m. Reception, 6.30; dancing 9.30 p.m. to 2 a.m. The dinner is open to all practitioners and their friends. Tickets (gentlemen 21s., ladies 15s., exclusive of wines) may be obtained of

any member of the committee, or of Dr. C. L. Batteson, dinner secretary, 228, Goldhawk Road, W.12, or of Dr. Robert J. Farman, Staple House, 51, Chancery Lane, W.C.2.

THE Prince of Wales opened, on December 12th, the new extensions at the Prince of Wales's General Hospital, Tottenham, consisting of three new wards holding seventy-two beds, a new theatre unit, and nurses' quarters, erected at a cost of £40,000.

A DINNER of the Queen's University Club, London, followed by a musical programme and dance, was held on the night of December 13th at the Criterion Restaurant, Piccadilly. The members and guests, of whom there were over a hundred present, were received by Dr. and Mrs. J. J. Redfern of Croydon. This reunion of Belfast University graduates and students was a great success. Membership, without nomination, was declared open to those eligible (all faculties) on payment of entrance fee and subscription, before March 1st, 1924, to the honorary treasurer, Mr. R. A. Kerr, 17, Wimpole Street, W. It is hoped that Queensmen and Queenswomen everywhere will join the club. Full particulars may be obtained from the honorary secretaries, Mr. W. McK. H. McCullagh, 152, Harley Street, W., and Dr. E. G. B. Calvert, 17, Wimpole Street, W.

A CHARITY ball, at which the Prince of Wales will be present, will be held under the auspices of the League of Mercy, at the Carlton Hotel, Pall Mall, W., on Wednesday, January 16th, 1924. Dancing will commence at 10 p.m. The price of single tickets, to include supper and light refreshments, is 30s.; they can be obtained from the Secretary, League of Mercy, 20, Cockspur Street, W.

At a meeting held on behalf of the Walworth Women's Welfare Centre on December 13th, Lord Buckmaster presiding, it was moved by Dr. Elizabeth Sloan Chesser, seconded by Dr. Binnie Dunlop, and resolved without dissent, that "This meeting represent to the Ministry of Health that it is desirable that no official opposition should be raised to the giving of birth control advice at any welfare centre, the medical officers of which are willing to give such advice."

DURING the recent Pasteur festival the University of Strasbourg conferred honorary degrees on Flexner and Loeb of the Rockefeller Institute, New York, Ramon y Cajal of Madrid, Perroncito of Turin, Welch of Baltimore, Ehlers of Copenhagen, and Bordet of Brussels.

THE fourth all-Russian congress dealing with health resorts will be held next month at Moscow.

THE next Congress of the French society of dento-facial orthopaedics will be held at the Paris Faculty of Medicine from January 19th to 21st, 1924. Further information can be obtained from the general secretary, M. de Nevreze, 20, Rue Mogador, Paris.

MESSRS. BURROUGHS, WELLCOME AND Co., and the BRITISH DRUG HOUSES, LIMITED, inform us that in accordance with the announcement by the Medical Research Council published last week (p. 1232) the price of insulin will be reduced on and after January 1st, 1924, to 12s. 6d. per phial containing 100 units (10 doses) in 5 c.c.m.

DURING 1922 the number of free venereal clinics in Germany was increased from 174 to 183. Of the 166,763 persons examined, 17,156 were found not to have any venereal disease; of the 77,307 who had some form of venereal disease, 28 per cent. of the men and 26 per cent. of the women were married.

NUMEROUS cases of acute poliomyelitis are reported to have occurred lately in Berlin, not only among children, but also among adolescents.

OF the 1,500 medical practitioners in Tokyo 1,000 have lost their practice as the result of the earthquake.

WATSON AND SONS, Sanic House, issue an exposure table in card form for estimating the x-ray exposures when using Coolidge tubes with either plates or double-coated films. The convenient form should make this of use to many x-ray workers.

SOVIET Russia was declared free from cholera - on October 3rd.

MR. J. W. WHEELER BENNETT, High Sheriff of Kent, has made a donation of £10,000 for the extension and improvement of the Kent County Ophthalmic Hospital, Maidstone.

DR. SPILLMANN, professor of dermatology and syphilis in the University of Nancy, has been nominated dean of the Faculty of Medicine in succession to the late Professor Meyer.

WE regret to hear of the death, on Christmas Day, of Sir Napier Burnett, K.B.E., M.D., Chief Executive Officer of the Joint Council of the British Red Cross Society and the Order of St. John of Jerusalem. He had been in ill health for some months. He was 51 years of age.

the contents of this bottle must be varied with the patient and the particular operation. I never use chloroform for children, and rely entirely on gas-oxygen-ethanesal, for I have used this last drug exclusively since its introduction by Drs. Wallis and Hewer, and am perfectly satisfied with it. I may remind you that this preparation consists of detoxicated ether with the addition of 2 per cent. mixed ketones. The research carried out by Dr. Wallis showed, amongst other things, that (1) the chief harmful impurity in ether was methyl mercaptan; (2) absolutely pure ether was not an anaesthetic; (3) ethylene or certain ketones added to pure ether provided a good anaesthetic, which on the average gave better results and less after-effects than ordinary ether. Most of the results obtained by Wallis have now been confirmed by other observers; in spite of some opposition, I consider that ethanesal is a distinct advance on ether.

For the young adults as well as the older people I use a mixture of ethanesal and chloroform in equal parts. I only use chloroform alone in the bottle when the diathermy or other cautery is being used in the mouth.

To those who are not familiar with this method the exceedingly small amount of ether or mixture that is used for a long case—for instance, a breast excision—will be something of a surprise, for it is quite an ordinary occurrence for from one to two drachms to be all that is necessary for the whole operation. It must, therefore, be obvious that an anaesthetic of this nature must entail less strain on patients than if they are given ether or chloroform or mixtures thereof, since we are giving the least possible quantity of toxic drugs. We know that nitrous oxide and oxygen are both non-toxic, and the amount of toxic drug in the mixture is so small as to be almost negligible.

Now for a moment let us turn to the actual administration of the anaesthetic. Having seen that the machine is in working order, that the main taps to the gas and oxygen cylinders are turned on, that the lamp is burning with a small flame against the base of the reducing valve to the gas cylinder, that the water bottle is filled to the proper level with warm water, and that the "ether" bottle contains such mixture as one desires for the case in hand, the gas and oxygen are then turned on and allowed to bubble through the water and thence to the gas bag in the proportion of approximately 10 to 1. As soon as the bag is three parts full the facepiece is applied to the face and the valve is turned over so that rebreathing starts from the beginning.

In a very short time the breathing will become deep, regular, and almost automatic; as soon as this occurs, the manipulation of the taps on the "ether" bottle the gases are made to pass over the surface of the fluid in that bottle, thus picking up a small proportion of either ethanesal or  $\text{CCl}_4$  vapour. After a few moments there will be another slight change in the breathing, which will become slightly snoring in character, and now, if the operation is an abdominal or nose and throat one, it is advisable again to manipulate the taps on the "ether" bottle and allow the gases to pass through the mixture, thus picking up a larger dose. By this time the patient is ready for operation, and in the majority of cases after the incision has been made through the skin the taps on the "ether" bottle can be turned back and gas-oxygen alone administered. When anaesthesia has been obtained the proportion of gases is altered to, in general terms, about four of gas to one of oxygen. In this method, as with all others, the airway must be kept open, and I have found that the introduction of an artificial airway greatly assists in obtaining good and quiet breathing.

The anaesthetist must now carefully watch the patient and be on the look-out for any changes in colour and any signs of a too light anaesthesia, such as swiftness or movement of limbs. The colour must be kept pink throughout, and should the anaesthesia be too light the ether tap must be turned on again for a minute or so. The eye great value, for it is quite possible to have a perfectly still and quiet patient with a brisk corneal reflex. The

only eye sign that I consider important is that should the pupil become widely dilated (due, I believe, either to too much gas, or too much mixture, or both), then the bag must be removed from the face, rapidly emptied, refilled with oxygen alone, and again applied to the face; after a few breaths the amount of oxygen can be reduced and gas added as before.

For a great number of operations it is quite unnecessary to give any more mixture, and the remainder of the operation is conducted under gas and oxygen. Given in this way the anaesthesia is excellent both for patient and operator, while the after-condition is extremely satisfactory. The patients readily regain consciousness, and in the majority of cases are not inconvenienced by nausea or vomiting. In addition to this they are rarely, if ever, conscious that they have had anything save gas and oxygen, for they do not, as a rule, have any taste or smell of ethanesal or chloroform. This lack of smell and taste is another point worth bearing in mind, for those working in the theatre—surgeons, anaesthetists, nurses, etc.—do not become impregnated with the smell and odour of ether or chloroform, an important point for their comfort. I find nowadays that, in using this method, after a long afternoon in a theatre I can leave feeling quite fresh and well, and the atmosphere of the theatre never becomes charged and laden with the vapour of ether and chloroform, as it often did formerly.

Operations such as amputation of the breast, hernias, rancoes, and the like, are quite easily done under gas and oxygen, and a very small quantity of either ethanesal or mixture; it is when one comes to the abdominal and nose and throat work that the difficulty begins.

For some time now many of us have been trying to get some combination to act as a really good relaxant for abdominal work. Gwathmey of New York uses a combination of ethyl chloride, ether, and chloroform, whilst McKesson of Toledo recommends a saturation in  $\text{N}_2\text{O}$ . It is hardly necessary to add that, in giving this combination for abdominal work, a certain amount of intelligent anticipation is necessary on the part of the anaesthetist, so that the surgeon may find the abdominal wall quite relaxed when the time for sewing up has arrived.

Let me make this a little clearer: assume that we are operating on a case of appendicitis. The anaesthetist is deepened at the beginning, so that the surgeon may easily and the appendix and bring it outside, but when once it is outside the anaesthesia need not be of a deep character, and so we only give gas and oxygen. Later on, when we see that in a few minutes the caecum will be returned to the abdominal cavity and the peritoneum sewn up, we again deepen the anaesthesia by turning on the mixture for a few minutes, and directly the peritoneum is stitched up we can again return to gas and oxygen alone. My experience of abdominal work done in the manner I have tried to explain is that the patient is indubitably better both during and after the operation when the combination of gas-oxygen-ethanesal-chloroform is given than after any other combination or single anaesthetic that I have so far encountered.

When I first began to use this method for nose and throat work I had nothing to guide me: so far as I knew my friend Gwathmey of New York was the only man who had tried to give gas and oxygen for throat work, and he had only begun, for the war cut his work short in New York and he came over to Europe. I will not weary you with an account of my earlier cases; many of them were failures, and it was only by sticking to it and having such a cordial co-operation in Mr. Harmer, our senior thoracic surgeon at St. Bartholomew's Hospital, that we have been able to evolve a method which I believe to be an excellent one for this type of operation, and one which is infinitely superior to anything that we have tried before.

Briefly, our technique is as follows: In regard to premedication, children have none, or at the most get 1/200 grain atropine; adolescents get morphine 1/6 grain and atropine 1/150 grain; adults get either Burroughs and Wellcome's "Hyoscine compound A" or "B," according to size. "Hyoscine compound A" contains hyoscyne hydrobromide

## Letters, Notes, and Answers.

As, owing to printing difficulties, the JOURNAL must be sent to press earlier than hitherto, it is essential that communications intended for the current issue should be received by the first post on Tuesday, and lengthy documents on Monday.

ORIGINAL ARTICLES and LETTERS forwarded for publication are understood to be offered to the BRITISH MEDICAL JOURNAL alone unless the contrary be stated.

In order to avoid delay, it is particularly requested that ALL letters on the editorial business of the JOURNAL be addressed to the Editor at the Office of the JOURNAL.

CORRESPONDENTS who wish notice to be taken of their communications should authenticate them with their names—of course not necessarily for publication.

AUTHORS desiring reprints of their articles published in the BRITISH MEDICAL JOURNAL are requested to communicate with the Office, 429, Strand, W.C.2, on receipt of proof.

THE postal address of the BRITISH MEDICAL ASSOCIATION and BRITISH MEDICAL JOURNAL is 429, Strand, London, W.C.2. The telegraphic addresses are:

1. EDITOR of the BRITISH MEDICAL JOURNAL, *Aitology Westrand, London*; telephone, 2630, Gerrard.
2. FINANCIAL SECRETARY AND BUSINESS MANAGER (Advertisements, etc.), *Articulate Westrand, London*; telephone, 2630, Gerrard.
3. MEDICAL SECRETARY, *Mediscera Westrand, London*: telephone, 2630, Gerrard. The address of the Irish Office of the British Medical Association is 16, South Frederick Street, Dublin (telegrams: *Bacillus, Dublin*; telephone, 4737, Dublin), and of the Scottish Office, 6, Rutland Square, Edinburgh (telegrams: *Associate, Edinburgh*; telephone, 4361, Central).

### QUERIES AND ANSWERS.

#### LICENCE FOR MALE SERVANT.

"L. B. S." employs a man on various work in connexion with the house, garden, delivery of medicine, and cleaning (not driving) of car. He is of opinion that the greater part of his work is in connexion with the practice, including therein (a) the cleaning of professional equipment and (b) work necessitated by the employment of other servants for professional purposes. The Ministry of Labour requires payment of unemployment contributions, but has apparently done so on the assumption that he is a "chanfeur and handyman," which is not entirely correct. Can licence duty be imposed?

\* \* In our opinion the answer to the question turns on whether (b) above is work done arising out of "employment in a personal, domestic, or menial capacity." We are not aware of any binding decision which covers the facts. The difficulty from our correspondent's point of view is the disjunctive "or" in the defining phrase. *Prima facie* domestic or menial work—for example, the cleaning of the surgery-maid's boots—is work in a taxable capacity although the ultimate object to be served is professional. On the other hand, to apply that construction rigidly would clearly involve considerable inequity—as, for instance, where a man was wholly employed on such work in a private nursing home. We suggest that our correspondent might approach the Ministry of Labour again stating the facts once more—including the fact that the servant does not drive the car. In all the circumstances we cannot advise him to resist the "licence" claim at present.

#### THE INFANT ANUS.

"G. R." asks what should be the size of the anus in an infant aged about 6 months. He has to treat a case in which he considers there is some stenosis, and proposes to use Hegar's dilators. He wishes to know what size (that is, number) of dilator the anus should be dilated to.

\* \* The normal anus of a child of 6 months should admit the little finger comfortably; gradual dilatation to twice that size if possible may be advisable. If the nurse passed an index finger daily that would be sufficient to prevent further stenosis. A finger would be preferable to a Hegar's dilator. Developmentally the condition represents a stage of an imperforate anus, and it would be well to exclude a septum or any abnormal opening into urethra, vagina, or bladder.

#### CHRONIC URTICARIA.

"HIBERNIA" asks for advice in the treatment of a case of chronic urticaria which has lasted six weeks. Methods of treatment tried, without success, include calcium lactate 15 to 20 grains t.i.d., injections of adrenaline hydrochloride, intestinal antiseptics, tinct. belladonnae, and a lacto-vegetarian diet. The usual soothing external applications give, of course, only temporary relief.

#### TREATMENT OF ACTINOMYCOSIS.

DR. W. SCOVEL SODEN (Winchcombe, Glos.) asks for suggestions for further treatment of the following case: Male, aged 37, actinomycosis of soft tissues of right side of face following a sinus left from incomplete extraction of a septic tooth four years ago. The present disease was first diagnosed two years ago. Has had potassium iodide in doses up to 4½ drachms a day, autogenous vaccines, and x rays. Abscesses are always incised and evacuated as soon as softening takes place. The condition is apparently no nearer being cured now than at the end of the first two months of treatment. The patient has seen many surgeons and physicians, but no recognized line of treatment has done any permanent good.

#### INCOME TAX.

##### First Year of Practice.

"R. L." is not aware of his predecessor's profits, as properly calculated for income tax purposes, and has been assessed for his first year in the practice on the basis of the gross bookings less expenses of that year, the amount of the correct three years' average being unknown.

\* \* The amount assessed cannot be said to be correct; at best it is presumably put forward as a probable approximation. If "R. L." can adduce any specific causes why his profits (true, not cash profits) should be more than his predecessor's they should be taken into account and the current year's figures modified accordingly if they are to serve as an estimate of the probable average. Even if that adjustment cannot be claimed some allowance should be made for the probable loss by bad debts to be incurred on the debts outstanding; for this purpose a detailed examination should be made by "R. L." of the debts outstanding, and any probable loss thereon treated as an expense of 1922.

### LETTERS, NOTES, ETC.

#### THE YEAR OF THE FIRST FOLIO.

MR. A. W. POLLARD has had the happy notion of sending to the *Times Literary Supplement* a list of the books published in London in 1623, the year of the appearance of the first folio edition of *Shakespeare*, which is, when all is said and done, the canon of his plays. The number of new works entered on the Stationers' Register in 1623 was 168. The list included ballads and news-letters or "Currants"; excluding these there were 145 entries of books; 88 of these (or 60 per cent.) dealt with religious subjects. There was only one book on law, but there were three medical entries, all of a popular kind. "They comprised," Mr. Pollard says, "(i) the second part of *Toby Venner's Via recta ad vitam longam*, (ii) *The Anatomie of Urines*, partly a translation, but containing 'a discourse of the lawlesse intrusions of parsons and vicars upon the profession of physicke' by the translator, James Hart, and (iii) 'a booke called *Punala, Ala Catholica*, or a compound ale, which is a generall purge for most infirmities.' To this last Master Hart may equally have objected, since it was written by 'Master Folkingham, gent.,' who presumably had no medical qualification."

#### CHOCOLATES.

THE Christmas parcel post has brought to this office a box containing an attractive assortment of chocolate and chocolate-coated sweetmeats, manufactured by Messrs. Cadbury Brothers, Ltd., in their hygienic workshops at Bournville. It is a fortunate thing that confectionery so popular nowadays among all classes can be had in so pure a form and at such moderate prices. Chocolate as a beverage was known to connoisseurs in the sixteenth century, but chocolate comfits were something of a rarity even in our grandparents' time, and the young people of to-day must often wonder how our ancestors contrived to exist before the great Quaker firms began to overspread the country with their delectable wares.

THE "Osteograph" supplied by Messrs. H. K. Lewis and Co., Ltd. (price 6s. 9d., post free), is a simple celluloid sheet by means of which the outlines of the bones can be rapidly and accurately drawn. The device is likely to be of use to students of anatomy and to any members of the medical profession who require such drawings for notes or demonstration purposes.

### BIRTHS, MARRIAGES, AND DEATHS.

The charge for inserting announcements of Births, Marriages, and Deaths is 2s., which sum should be forwarded with the notice not later than the first post on Tuesday morning, in order to ensure insertion in the current issue.

#### MARRIAGE.

PLACE—TURNER.—On December 22nd, at St. Margaret's Church, Burnage, Thomas Byron Place, junr., L.D.S., eldest son of Thomas Byron Place, L.D.S., of Crewe, to Mary Turner, M.B., Ch.B., D.P.H., eldest daughter of the late Martin Turner and Amy Turner of Manchester.

#### DEATHS.

BISSET SMITH.—On December 5th, at his residence, 23, Willow Road, Hampstead, N.W.3, John Bisset Smith, M.A., M.B., Ch.B., aged 74 years.  
GARDNER.—On October 8th, Robert Irvine Gardner, M.B., of London Road, Enfield, after an operation.  
WORTS.—On December 23rd, at Fordham Lodge, Fordham, Charles James Worts, M.R.C.S., L.S.A., aged 80 years.

# EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

### 468. Underfeeding and Disease.

H. CURSCHMANN (*Muench. med. Woch.*, November 16th, 1923, p. 1579) describes the effects of the hunger period in Germany during and since the war on various forms of disease. The author considers that the endocrine glands and the vegetative nervous system suffer especially as the result of underfeeding. The thyroid gland is the one most affected, and during this period of underfeeding the author states that the number of cases of complete or incomplete hypothyroidism was considerably increased (mild cretinism, thyrohypoplasia, congenita, mild hypothyroidism, and true myxoedema of the adult). The physiological menopause has not infrequently been followed by myxoedema. Atrophy of the thyroid gland, to a greater extent than atrophy of other organs, has been found *post mortem* in cases of hunger oedema, the most severe form of hunger disease, the oedema in which may be removed by giving vitamins, albumin, fat, and lime salts in larger quantities, or by giving thyroïdin. The usual forms of obesity (due to overfeeding, indolence, beer, etc.) improved greatly during this period of underfeeding, but cases of obesity of endocrine origin did not do so, and in some of these cases the underfeeding was followed by increase of the obesity. In contrast with the increase in the number and severity of the cases of myxoedema, there has been a diminution in these respects in the cases of Graves's disease. Henke's statistics, Hamburg, 1903-14: Cases of Graves's disease, 217; 1915-20, only 42.) Curschmann recommends, therefore, limitation of the flesh food in the diet, and warns against overfeeding in Graves's disease. In diabetes mellitus the underfeeding increased the tolerance for carbohydrates in large numbers of cases. The cases of hunger osteopathies were numerous (estimated by Römer and Fromme as 30,000 amongst adults in Germany in 1922). These osteopathies appeared in the young chiefly in the form of late rickets; in older persons, especially women, the symptoms were frequently those of osteomalacia. Rickets in children was more frequent and severe in the hunger period.

### 469. Meningeal Complications of Facial Erysipelas.

M. PINALIE (*Thèse de Paris*, 1923, No. 44), in a thesis containing the histories of 13 cases, of which two were observed by himself, remarks that although nervous symptoms, especially delirium and convulsions, are frequent in facial erysipelas, they can seldom be shown to be of meningeal origin. The rarity of meningeal complications in erysipelas as compared with other acute infections, especially pneumonia, is attributed to the following causes. First, a meningeal localization is favoured by the presence of septicaemia, which is rare in erysipelas owing to the streptococcus passing into the lymphatics and not into the blood. Secondly, lesions in the immediate neighbourhood, such as sinusitis, otitis, orbital suppuration, and naso-pharyngeal inflammation, which are apt to cause meningitis by spread of infection, are rare in facial erysipelas. Thirdly, a predilection for the meninges such as is shown by the meningococcus or pneumococcus is not exhibited by the streptococcus except in association with other organisms, especially the pneumococcus. The meningeal manifestations of erysipelas chiefly occur in the form of suppurative meningitis, as in 12 of the cases collected by Pinalie, the remaining case being one of serous meningitis. The symptoms, which as a rule develop during the acute stage of facial erysipelas, do not present anything to distinguish them from those of other forms of acute meningitis. With the exception of the case of serous meningitis, all Pinalie's cases proved fatal.

### 470. Bismuth in the Treatment of Syphilis.

L. K. MCCAFFERTY (*Arch. Derm. and Syph.*, October, 1923, p. 469) reports 25 cases of syphilis at different stages treated by bismuth, and the conclusions at which he has arrived as the result of his observations in this method of treatment. The preparation used was potassium and sodium tartrite-bismuthate; it was made up in ampoules of 2 c.cm. containing 20 cg. of bismuth in oil suspension, and from twelve to sixteen injections, given every four days, comprised a course. He found that bismuth in primary and secondary syphilis was as effective as arsenical preparations, though clinically and serologically it was less rapid in action. In three primary cases treated with bismuth the chancres cicatrized in five days, spirochaetes disappeared within ten days, and

alolenopathy within sixteen days, while the Wassermann reaction remained negative. The lesions and symptoms in the secondary cases treated rapidly improved, and while in three of them the Wassermann reaction was delayed, a negative reaction was obtained in the fourth case after only one course of injections. Only one gummatous case was treated, and here the gumma healed in three weeks, a negative Wassermann being present after two courses of bismuth. In five Wassermann positive asymptomatic tertiary cases the reaction was reduced in all except one—in three of them after the second course of injections. One case of tabes with tertiary lesions was of special interest in that the Wassermann reaction, negative before bismuth therapy, became positive after the second injection—possibly a provocative effect. Cases of tabes and others presenting incipient paralysis all showed improvement in subjective symptoms, which usually disappeared in the tabes cases after the first or second injection. The author hopes that the above two classes of patients will submit to spinal puncture in order that they may be followed up and a clearer estimate of the relative value of bi-muth be obtained. He considers that there is a definite indication for bismuth in positive Wassermann cases and in those possessing an idiosyncrasy to arsenic. The pigmentation at the gingival borders and the ulcerative stomatitis frequently produced by bismuth are to be regarded as negligible, disappearing in from two weeks to a month after cessation of treatment. Monthly urine analysis is recommended. The author regards bismuth, separately or in combination with arsenic and mercury, as of considerable value in the treatment of syphilis.

### 471. Malarial Inoculation Treatment in General Paralysis.

W. WETGANDT (*Klinische Wochenschrift*, November 19th, 1923, p. 2164) records his results in the treatment of general paralysis of the insane by inoculation with malarial parasites, according to the method of Wagner-Jauregg. The author has treated nearly 300 patients by this method, and gives his statistics. Two series of earlier statistics are combined with a third series of the more recent statistics in 170 patients inoculated over a year ago. The patients after inoculation can be classified in five groups. In one group are those in which death from the disease, or its complications, occurred in spite of treatment; in the second group are those in which no improvement occurred; in the three other groups more or less improvement was recorded. These results, though not conclusive, are certainly worthy of the careful consideration of all those who have to treat this grave disease, since the majority of the author's patients, after this inoculation treatment, were able to return to work. Short spontaneous remissions of symptoms in early general paralysis are well known, but the author considers they are not so marked nor of such long duration as those which follow malaria inoculation: 1 to 4 c.cm. of the blood of a patient suffering from tertian malaria is employed for the purpose of inoculation. Improvement in the symptoms of general paralysis is described: the rapid and the juvenile forms of the disease are not influenced, and in other mental affections, as also in disseminated sclerosis, no results were obtained by this treatment.

### 472. Congenital Mitral Stenosis with Patent Foramen Ovale.

A. CRAMER and ED. FROMMEL (*Arch. Mal. du Cœur, des Vaisseaux et du Sang*, August, 1923, p. 561) describe the case of a woman, aged 41, small but well proportioned, admitted to hospital six weeks before death. She had a severe paroxysmal cough, blood-stained sputum, violent thoracic pain, oedema of ankles, and oliguria, but at no stage of the illness was cyanosis observed. The area of cardiac dullness was greatly increased; it extended considerably beyond the right sternal border, while the apex beat was felt in the seventh left intercostal space in the anterior axillary line. A skiagram showed a greatly enlarged heart, while the thorax was so small that the heart was in contact with the vertebral column, producing definite dullness in the intrascapular region. There was a presystolic and systolic thrill and a short presystolic crescendo rumble followed by a systolic bruit conducted into the axilla. At the base the aortic sounds were feeble, while in the pulmonary area they were accentuated. There was epigastric pulsation and also marked arrhythmia. The liver extended 2 inches below the costal margin; it was firm, smooth, and non-pulsating. There was no history of rheumatism and no evidence of syphilis.

Dr. JOHN C. BEDWELL of Chesterfield, who died on June 13th, aged 59, was educated at the University of Edinburgh and took the diploma at the University of Edinburgh and the Middlesex Hospital. He graduated B.Sc. Lond., and took the diploma at the University of Edinburgh and the Middlesex Hospital. He was formerly an assistant school medical officer in Sheffield. Dr. Bedwell was held in high esteem in Chesterfield as a hard-working, conscientious medical officer. He was very popular with all members of the school staffs and with the members of his own profession with whom he came in contact.

### Libel or Legal?

#### LIBEL OR A MEDICAL REFERENCE

Dr. STEWART WATKINS, of Old Elvet, Durham, a medical referee under the Workmen's Compensation Act, had given the subject of criticism contained in a pamphlet signed by the Durham Miners' Association, and circulated to the members of the Houghton Lodge and also to the secretaries of other lodges of the Durham Miners' Association. Dr. Plummer referred to this pamphlet in the Medical Defence Union, which decided to sue the signatories and the printers for libel. The case Plummer v. Gregory and Others was heard by Mr. Justice Greer and a jury at Durham Summer Assizes, and the proceedings terminated in a verdict for Dr. Plummer, who was awarded £100 damages.

The pamphlet was headed "Protest against a medical reference," and commenced:

"We wish to draw your attention again to medical referees' decisions on compensation cases (especially to Dr. S. Plummer, of Durham)... For a considerable time we look upon these decisions as a mockery to the court ourselves, and we were compelled to send them to Durham, and not one case was sent by the judge to a medical referee. What? Because we were able to produce medical evidence and the judge examined all witnesses of the accident, and was therefore able to give a fair decision. We ask you to examine the reports of Dr. Plummer and judge for yourselves."

The pamphlet went on to instance four cases reported upon by Dr. Plummer, in the last of which Dr. Plummer said: "There is, however, a permanent disability and he is not able to make full use of his left hand, and his condition is such that he is fit for employment as a porter but he could not do heavier work which involves the full use of his left hand."

The pamphlet proceeded: "It is evident that he is putting, means 'pulling' out, and surely we ought to defend men who unfortunately happen to have accidents in the mine and whose future happiness, and destiny, depends upon an Act of Parliament which allows a medical referee who, lacking practical experience, gives each ridiculous reports as stated above."

The judge held that the occasion was privileged—the pamphlet having been addressed only to members of the Durham Miners' Association—and that the comment so far as fair. But there followed a vital sentence which the judge considered should be left to the jury to ascertain whether the defendants were actuated by malice, in which case, of course, the privilege would be lost.

"We now strongly object to any further cases going before Dr. Plummer, and cases at our colliery are held up through our decision, and we respectfully ask your members to help us to turn this man off the medical referees' list, because if it had been vice versa he would have been struck off the list years ago."

The printers apologized, but, as the judge said, in the eyes of the law people who take part in printing or circulating a libel are responsible equally with its authors, and a jury cannot distinguish between the different defendants as to damages.

The allegations contained in the pamphlet were dealt with by his statement that he had lived in a mining district all his life, and that he had many times been down mines to see work that had been offered to workmen.

The defence was itself an exonerator of Dr. Plummer. It revealed the fact that the Houghton Lodge were so dissatisfied with the method of working the Workmen's Compensation Act that they not only issued the pamphlet complained of but also debated a resolution urging the abolition of medical referees altogether. Thus, in setting forth their objections to medical referees, the Houghton Lodge were so dissatisfied with the method of working the Workmen's Compensation Act that they not only issued the pamphlet complained of but also debated a resolution urging the abolition of medical referees altogether.

### Medical Refusals

The Fellowship of Medicine has arranged a course of lectures on medical and surgical diseases of children by the members of the staff at the Royal Waterloo Hospital from July 16th to August 3rd. Those taking part in the course will have an opportunity of attending the outpatient department, wards, and operations. A special course in dermatology will be given by the members of the staff at the Hospital for Diseases of the Skin, Blackfriars, from July 16th to 22nd inclusive. Instruction will be given in the outpatient department every afternoon from 2.30 p.m. to 4 p.m. on Monday, July 16th, and Wednesday, July 22nd. The course will also include a general clinic on Tuesday and Friday each week from 5.30 to 7 p.m. The fees for the courses are 3 guineas and 2 guineas respectively, and application for copies of the syllabus and tickets of admission should be made to the Secretary to the Fellowship of Medicine, 1, Wimpole Street, W.1.

The British National Council for Mental Hygiene, which seeks to emulate the achievements of the American, Canadian, and French Councils in the promotion and preservation of the mental health of the community, is making an appeal for funds. The first essential is held to be the prevention and cure of those minor disorders which may develop into mental instability. It desires to co-operate with societies interested in industrial psychology, mental after-care, and mental deficiency and delinquency. It is anxious to facilitate the study of psychology and psychiatry on broad and temperate lines and to put into a position to encourage scientific research. Donations should be sent to the honorary treasurer, Lord Southborough, at the offices of the National Council for Mental Hygiene, Room 55, Windsor House, Victoria Street, S.W.1.

The Dental Board of the United Kingdom is arranging, for persons registered under the Dentists' Act, 1921, short introductory courses of lectures and demonstrations at Cardiff, Peterborough, and Dublin, and will make similar arrangements in Glasgow and Belfast if courses are not given at the dental schools there. Three lecturers will be appointed for each course and will receive a fee of 5 guineas for each lecture, with travelling and hotel expenses. Applications by lecturers should be received by the Dental Board (44, Hatfield Street, London, W.1) not later than September 1st. Entrants for a course will be charged a fee of 1 guinea, but this will be returned at the end of the course to those who attend 75 per cent. of the lectures.

The honorary secretary of the British Society of Dental Surgeons (11, Chandos Street, W.1) asks us to state that a meeting of holders of the L.D.S. diploma will be held on Friday, July 20th, at Steinway Hall, Wigmore Street, at 7.45 p.m., to consider the action of Liverpool University in offering a modified curriculum for the L.D.S. diploma to dental students (1921) and the possibility of such action by other educational authorities.

FOURTH DAY will be celebrated at Epsom College on Monday, July 30th, when Lord Louis Mountbatten will give away the prizes.

A *Medical Refusals* is the title of a journal for general practitioners, founded in Vienna in 1911. Since the beginning of this year an English translation has been published monthly. It appears to be designed mainly for the use of the profession in America, the subscription (2 dollars) being payable to the American Express Company, 65, Broadway, New York.

At the *post-mortem* examination enormous hypertrophy of the right ventricle and auricle with hypoplasia of the left side of the heart were found. There was advanced mitral stenosis without incompetence, but the tricuspid orifice admitted four fingers easily. There was a large aperture in the inter-auricular septum measuring 3.5 by 2 cm. The dilated pulmonary artery measured 90 cm. in circumference, while the aorta measured only 36 cm. The authors consider that in this case the mitral stenosis was due to defective foetal development, as there was no evidence of endocarditis; this obstruction caused the blood from the left auricle to pass through the septum into the right side of the heart, thus preventing the closure of the septum after birth. They quote a number of similar cases recorded by other authors; two of these resembled the present case in that there was no cyanosis at any period. They find it difficult to explain this phenomenon.

## Surgery.

### 473. Incarcerated Intersigmoidal Hernia.

W. SMITAL (*Zentralbl. f. Chir.*, September 29th, 1923, p. 1478 refers to Erkes's recently published case of this condition (*Zentralbl. f. Chir.*, No. 8, 1923), and records a similar case. A master smith, aged 60, had been in good health until a sudden attack of severe colicky pain occurred. When seen two days later he had passed neither faeces nor flatus, and complained of nausea; pronounced emphysema was present. The abdomen was distended and tympanitic, and there were three transverse cord-like swellings, which appeared to be distended coils of small intestine; there was no visible peristalsis. The whole abdomen was slightly tender on pressure; rectal exploration showed only tenderness in the recto-vesical pouch. As oil and soap enema produced no result and the patient's condition was desperate, operation was decided upon, and a median infraumbilical laparotomy under local anaesthesia was performed. Distended coils of small intestine with numerous subperitoneal haemorrhages extending for over 2 feet were seen; on raising these coils the serous coat gave way in four places; these lacerations were sutured, one of the distended coils was incised, and a small rubber drainage tube inserted and secured with a purse-string suture. Through this a large quantity (3½ litres) of thin dark-coloured faeces was evacuated and the incision closed with three rows of sutures. It was then found that the coils of small intestine had passed through a ring-shaped opening in the mesosigmoid; this ring was incised and the incarcerated bowel was easily removed from a cavity as large as a man's fist and 60 cm. in depth; there were small haemorrhagic infarcts in the mesentery of the strangulated bowel. Irrigation with warm NaCl solution induced slight peristalsis. As the patient's condition precluded a resection of the bowel, the abdominal wound was closed in three layers under ether anaesthesia. In spite of stimulating intravenous and intra-rectal injections the patient died ten hours after operation. At the *post-mortem* examination fibrinous peritonitis following recent incarceration of small intestine in the meso-sigmoid foramen (persistent intersigmoidal recess) was found; the small intestine was definitely distended, the peritoneal coat reddened and dull; the lowest part of the ileum measured 70 cm. in diameter. Smital says that this type of hernia may occur when the sigmoid is abnormally long and there is a large persistent intersigmoidal recess. A list of published cases is appended.

### 474. Visceral Injuries.

H. B. SCHOENBERG (*New York Med. Journ. and Med. Record*, October 17th, 1923, p. 500) states that these injuries, which follow heavy blows with a blunt instrument or compression as when a patient is run over by a vehicle, are frequent enough to merit serious consideration. Schmitt points out that, whereas the mortality following expectant treatment amounts to 97.5 per cent., early operation has greatly reduced the death rate. Temporizing measures for observation and more accurate diagnosis are inexcusable, as the mortality (reported by several eminent surgeons) is only 45 per cent. in all cases operated on within twenty-four hours of receipt of the injury. Schoenberg describes the symptoms and physical signs as follows: (1) Shock is not a prominent symptom, except in injuries of the upper abdomen, with severe haemorrhage. (2) Pain and tenderness are constant, deep-seated, diffuse, and radiating. (3) Initial vomiting almost always occurs, and is of no diagnostic value, unless persistent. (4) Rigidity; muscular spasm is a most valuable sign—it is present from the onset, is rather diffuse, and gradually increases. (5) Tympanites appears late, with disappearance of liver dullness and peritoneic effusion. (6) An increasing pulse rate indicates intra-abdominal mischief. (7) The temperature is of no special diagnostic value; it is at first

subnormal, but rises with onset of peritonitis. (8) The respiration is usually rapid, shallow, and of definitely "thoracic" type. The author concludes that the degree of violence bears no constant ratio to the degree of injury; the greater the injury to the abdominal wall the less usually is that of subjacent parts.

### 475. Thyroid Tumours at the Base of the Tongue.

G. PORTMANN (*Arch. de med., cir. y esp.*, August 18th, 1923, p. 283) notes that until recently thyroid tumours at the base of the tongue were regarded as very rare, but of late an increasing number of cases have been published, so that Doré, in his recent Bordeaux thesis, was able to collect 102 cases, including the first, which was recorded by Hickman in the *Pathological Transactions* in 1879. The symptom consist in the sensation of a foreign body at the base of the tongue, which usually produces a constant desire to swallow and excessive salivation. When the tumour has reached a certain size the patient suffers from a constant dry cough, which may be paroxysmal, and from difficulty in swallowing. Haemorrhage is said to be frequent, although Portmann has never observed it. In the early stage nothing is to be seen when the mouth is opened, but laryngoscopy shows a smooth tumour of varying size occupying one or other side of the base of the tongue. In some instances a swelling may be discovered on external examination of the submaxillary region, or beneath the angle of the jaw. The condition must be distinguished from lipoma, fibroma, angioma, gumma, dermoid cyst, and cyst of the thyro-glossal duct. The only treatment is surgical, and excision is all the more likely to be successful the earlier it is performed.

### 476. Spinal Anaesthesia with Stovaine-Caffeine.

T. JONNESCO (*Bull. et Mém. Soc. Chir. de Paris*, October 23rd, 1923, p. 1132) describes the results obtained by using a solution of stovaine and caffeine for spinal anaesthesia. He originally used a dose of 50 cg. of caffeine for low injections in the dorso-lumbar regions, but retention of urine often resulted, so he reduced the dosage by half, with satisfactory results. For high injections in the cervico-dorsal region the full dose of caffeine gives excellent results. He uses a dose of 5 or 6 cg. of stovaine in operations on the head and neck without ill effects. The amount of stovaine used varies with the age, general condition of the patient, and length of the operation. Some writers are opposed to the use of the caffeine solution on the grounds that it produces a stage of excitement in the patient, is dangerous, and does not prevent bulbar complications. The author, however, finds this solution quite satisfactory, the only complication he has met with being retention of urine. Good results cannot be obtained with stovaine alone, or with stovaine and strychnine; further, the caffeine appears to increase the anaesthetic effect of the stovaine in long and difficult operations. He has successfully performed the operation of gastro-enterostomy with the aid of these solutions. Complete anaesthesia can be procured without the post-operation headache sometimes seen after the use of novocain. This method has been employed in 593 cases of spinal anaesthesia with success and without complication. He has used spinal anaesthesia in a total of 5,481 cases without a death or accident.

### 477. Sulphur Dioxide Treatment of Wounds and Ulcers.

ROTTSAHL (*Deut. med. Woch.*, September 21st, 1923, p. 1212) advocates a treatment which has hitherto been mainly confined to the sphere of the veterinary surgeon. It consists of applying an ointment or a liquid impregnated with sulphur dioxide to wounds and ulcers and to whitlows and carbuncles after they have been incised. The author's experience with this treatment covers a period of about a year, during which he has given it in about 60 cases. In no case was any harm done, and in several marked improvement resulted; sluggish varicose ulcers which had persisted for years responded within a fortnight in a remarkable manner. The first effect of an application of powder impregnated with sulphur dioxide is a tingling, stinging sensation, which is not, however, worse than that associated with the application of tincture of iodine to a raw surface. The tissues respond at first by an increased discharge and become less sodden and swollen; the discharge, at first dirty brown, becomes light yellow, the offensive smell and sloughs vanish, the surface of the wound becomes flatter, and there is a rapid growth of new epithelium. The sulphur dioxide is liberated as soon as the powder or liquid comes into contact with a wound or ulcer, and to prevent the gas escaping too soon the powder or liquid should be covered by a non-porous dressing such as some indifferent ointment. The author uses two strengths of sulphur dioxide powder and two strengths of sulphur dioxide liquid, the two preparations being sold under proprietary names by a firm of German chemists.

EPITOME OF CURRENT MEDICAL LITERATURE.

## Medicine.

Erythema Nodosum and Tuberculosis.

*A. de CROUZEY (Revue de Médecine, May 29, 1876, p. 252).* asserts that erythema nodosum is a syphilitic affection, and as such may arise from various intoxications and infections; it is not, in his opinion, a morbid entity, but the cutaneous expression of a toxic infection, which, in approximately three-fifths of the cases, is of tuberculous origin. While admitting that erythema nodosum usually runs a singularly benign course, Dutoeur observes that there may be more or less persistent fever with generalized pain and arthritis. Visceral complications are exceptional, but pulmonary and cardiac lesions have occurred. Teissier and Schneider have observed bruits (usually transitory) in 12 out of 44 cases. Convalescence may be either rapid or prolonged and followed by persistent anaemia. It is sometimes interrupted by the occurrence of a tuberculous complication. Generally, when the temperature has been high and persistent, there is greater reason to fear the onset of tuberculosis. An apparent recovery may be deceptive, as after the lapse of some months, possibly after a year, tubercle bacilli may be found. Because the onset of tuberculosis is apparently delayed, some observers believe that its occurrence is only a coincidence, or that the debility following tubercle bacilli. Against this view the great frequency of post-erythematous tuberculosis is cited. Dutoeur refers to Leclapart, himself, who observed a case of tuberculosis, which he had noted at the time of the erythema nodosum, and had already published. He states that the erythema nodosum is a proof that this disease is not always a manifestation of rheumatism. Erythema nodosum occurs in many diseases, especially leprosy, malaria, mumps, scarlet fever, diphtheria, etc., and that this disease is not infrequently accompanied by certain clinical lesions similar to those of the erythema nodosum, which we have seen pointed out by Crocq, various authors, and we have already mentioned. Against this view the great frequency of post-erythematous tuberculosis is cited. Dutoeur refers to tubercle bacilli.

27. Duodenal Intubation in the Diagnosis of Chronic Pancreatitis

P. CARLSON and H. GARTLINGER (*Pitts mtd.*, May 19th, 1923, p. 451) state that in cases of jaundiced duodenal intubation may yield information on the following points: (1) The amount of pigment and bile salts in the duodenal fluid. As a rule the fluid is colorless, containing neither pigment nor bile salts. (2) The amount of pancreatic fermentations in the duodenal fluid. (3) The presence of blood in the duodenal fluid. Intestinal haemorrhage indicates duodenal ulcer, and continuous haemorrhage cancer. Duodenal intubation enables one to determine the site of the haemorrhage and to eliminate gastric and intestinal haemorrhage. (4) The presence of certain cells in the fluid. In duodenal ulcer a considerable quantity of leucocytes may be found in the centrifugized fluid, while in cancer fewer dysplastic cells may be present. (5) The presence of micro-organisms in the fluid. The authors have employed duodenal intubation in cases of typhoid in which the typhoid bacilli were found in cases of typhoid carriers. Their conclusions are as follows: (1) The duodenal intubation is as easy as the other diagnostic procedures. (2) The duodenal fluid shows a simultaneous retention of bile and pancreatic juice which will indicate the presence of bile and pancreatic duct and pancreatic disease. (3) The presence of blood, especially clots, in the duodenal fluid, the obstruction there is retention of bile and pancreatic juice for longer than 12 hours. (4) The amount of the pigment and bile salts present in the fluid will indicate the amount of bile and pancreatic duct and pancreatic disease.

## Radiology and Electrology.

### Opothorapy by Radiation.

578. SCHMITT (*Bull. Soc. de Ther.*, October 10th, 1923, p. 232) remarks that the effects of radio-activity differ according to the degree of sensitiveness of the cells on which they act and the quantity of the rays employed. In dealing with each variety of cells, whether healthy or diseased, there are favorable, indifferent, dangerous, or toxic doses. Large doses are employed for the treatment of fibroids and malignant growths and moderate doses for dulling the activity of a fatigued or overexcited organ, while very small doses have a stimulating action. Schmitt shows that these small doses, to which attention has only recently been directed, may exercise the same restorative action on the glands of internal secretion as is usually produced by drugs. Radiotherapy, however, possesses the advantage over drug treatment of not introducing any foreign substance into the body and thereby not causing any symptoms of intoxication. Schmitt records nine cases in which considerable improvement took place as the result of x-ray treatment of certain glands of internal secretion. The first case was that of a weakly tubercle infant aged 6 months who derived considerable benefit from three radiations at one month's interval of the thymus of three minutes' duration. In three cases of menorrhoea the menses were restored within a period ranging from eight days to three months after irradiation of the ovary. Five cases were examples of an early menopause in women aged from 36 to 43, in whom the monthly periods were restored by the same method.

### 579. Elevation of the Diaphragm: Unilateral Phrenic Paralysis.

J. M. W. MORISON (*Arch. Radiol. and Electrother.*, September, 1923, p. 111) discusses the differential diagnosis of elevation of the diaphragm. A temporary elevation, he explains, is frequently caused by gaseous distension of the stomach, and is often seen in carcinoma of that organ. It differs from the permanent variety in that the movements of the affected diaphragm are never reversed—that is to say, there is no paralysis. Permanent elevation may be congenital or acquired. Loss of movement of the chest wall at the base and apex of the lung suggests that there is congenital unilateral paralysis of the diaphragm, whereas increase of movement on one side suggests an acquired corresponding condition. That movements are not lost on the affected side in the acquired type is due to expansion of normal lung and to the use of extraordinary muscles of respiration. The causal condition may be injury or disease. The author points out that Petit's eventration and unilateral phrenic paralysis are indistinguishable apart from a definite lesion of the phrenic nerve. Permanent elevation of the diaphragm is to be differentiated from (a) hernia, (b) localized hydro- or pyo-pneumothorax, (c) subphrenic or subhepatic abscess. In hernia the x-rays show an elevated irregular broken line extending across the hemithorax; underneath this line lung tissue may or may not be seen. The stomach contents may reach above the line of the cardia, palpation of the abdomen producing a rippling of the surface. In small herniae reversed movements during respiration are seen, but movements may be absent in large herniae. The author does not lay much diagnostic stress on the presence or absence of the colon in the picture: it may be present or absent in both herniae and eventration. Of the utmost importance is examination of the stomach by the bismuth meal, which should settle the diagnosis. Hydro- or pyo-pneumothorax and subphrenic or subhepatic abscess should cause little difficulty. In all of them the x-ray picture will easily reveal the condition present, the differential diagnosis from Petit's eventration resting on the presence in the latter of an unbroken bow line extending high into the thorax with reversed movements unless adhesions have formed. In eventration, also, the level of free fluid in the stomach is that of the cardia, and the bismuth meal will reveal the gastric deformities so frequently present in the condition.

### 580. Treatment of Prostatic Hypertrophy by X Rays.

M. DEVOIS (*Journ. de Radiol. et d'Electrol.*, September, 1923, p. 460) considers that although Gantier and others have had good results since 1901, x-ray treatment of prostatic hypertrophy has not received the attention it deserves. Prostatectomy is a serious operation, and the most recent statistics show a mortality of 10 per cent. Many patients suffer from renal, cardiac, or pulmonary diseases which increase the risk. Devois therefore urges that x-ray treatment should be tried in cases where these diseases, arterio-sclerosis, diabetes, or leucophilia are present. Moreover, many patients refuse

operative treatment; others have subjective and functional symptoms, accompanied by few, if any, objective signs. Devois divides these cases into three classes: (1) Typical adenoma; (2) fibro-adenoma (the mixed type = glandular proliferation with hyperplasia of connective tissue); (3) true fibroma where the gland structure has been destroyed by fibrous hyperplasia. These three types may be recognized by rectal and urethral examination. The third class is unlikely to be improved by x-ray treatment, but cases of adenoma or of fibro-adenoma are often greatly relieved if not completely cured. Devois observes that if x-ray treatment fails it does not diminish the prospect of successful surgical treatment, and that in advanced cases with very indurated prostates, valuable time should not be lost by fruitless x-ray treatment. In less advanced cases x-ray treatment has a definite value; it is most suitable in commencing hypertrophy, and any good results obtained persist. Devois recommends perineal irradiation in either the "gynaecological" or the genopectoral position. In either position the testes should be carefully protected from the x-rays.

### 581. Failure of Radiotherapy in Malignant Disease.

P. SIPPEL and G. JAECKEL (*Munch. med. Woch.*, September 21st, 1923, p. 1191) review the results of eleven years' practice of radiotherapy at the Berlin University gynaecological clinic. They find that the confident claims made by the pioneers of the treatment have not been realized, and the earlier enthusiasm has not been justified by results. They state that, in spite of improvements in technique and apparatus, recent results show little improvement. The authors tabulate their results, dividing them into two periods—that is, prior to May, 1918, and from that date until the present time. Before May, 1918, they treated exclusively with x-rays 71 cases of primary carcinoma and 83 cases of recurrence after operation. Since that date they have carried out 144 "prophylactic irradiations" as a preliminary to operation. Their most favourable figures show 11 per cent. of cures in 9 cases of breast cancer and 15.73 per cent. of cures in 38 cases of recurrence of the same disease. The results of prophylactic irradiation before operation in cases of cancer of the cervix and of the ovary are much more satisfactory. The authors report cures in 53.7 per cent. of the former and 35 per cent. of the latter. Also in inoperable recurrences in breast cancer they have found some improvement in 15.7 per cent. They observe that the explanation of these frequent failures must be sought either in the overestimation of the power of x-rays to penetrate deeply, with consequent errors in dosage, or that the sensitiveness of the cells of the more malignant tumours to x-rays has been overestimated. They refer to the work of Dessauer and others who have endeavoured to discover physical data and formulae based on the penetrative power of the rays at different depths, but they admit that the results obtained hitherto are lacking in accuracy. They agree with the majority of German writers in their rejection of such methods of dosimetry as "Kienbock's strips" or Sabouraud's pastilles; they prefer to estimate the dosage by the degree of erythema of the skin. They have found that the same Coolidge tube may vary greatly at different periods in the amount of x-rays which it gives out, and they recommend that this "output" should be frequently verified. Several tables and a formula for calculating the dosage of x-rays are given.

## Obstetrics and Gynaecology.

### 582. Axial Torsion of the Myomatous Uterus.

ACCORDING to FLECRENT (*Bull. Soc. d'Obstet. et de Gynecol. de Paris*, 1923, v, p. 372), the symptoms of axial rotation of a myomatous uterus show an acuteness which varies directly with the breadth of the attachment of the base or pedicle of the tumour to the untwisted portion of the uterus. In one case the uterus had become rotated through 180 degrees on a long and thin cervix; the patient had experienced no pain and came to the operation table only because blood-stained vaginal discharge occurring twelve years after the menopause gave rise to suspicion of malignant degeneration of her myoma. A second patient had symptoms suggesting intestinal obstruction; examination showed a large myomatous uterus and a fluctuating tumour in the posterior cul-de-sac which was thought to be a twisted ovarian cyst. At the operation the uterus was found twisted through 120 degrees around the cervix, which contained myomata; the site of the torsion was a broad zone of the myomatous mass, and above it intense venous stasis and peritoneal reaction had led to the acute clinical symptoms. In this patient the rotation had occurred during sleep.

## 483. Treatment of Perforated Uterus.

THE uterus may be perforated during the evacuation of an incomplete abortion, and it was the admission of such a case to hospital which led E. SCHWAB (*Zentralbl. f. Gyn.*, September 8th, 1923, p. 1451) to go thoroughly into the question of the proper treatment. The author thinks that each case should be treated on its merits; thus in the case of a perforation which has occurred in hospital under aseptic conditions, if there are no remnants of the abortion *in utero* and the perforation is small, the danger of considerable internal bleeding is but little, and the patient should be treated by rest, ice-bags, and opium. As regards operative treatment, laparotomy should be performed in all cases of doubt as regards sepsis and the degree of perforation. If the perforation is large, if its edges are mutilated, or the uterine tissue much torn, if there is any possibility of infection, or if a piece of placenta still remains which would require further curettage, hysterectomy is recommended. If the perforation is fresh, and excision and disinfection of the scar can be carried out, sutures may be applied.

## 484. Experimental Transplantation of Endometrial Tissue.

V. C. JACOBSON (*Amer. Journ. Obstet. and Gynecol.*, September, 1923, p. 257) records experiments on rabbits which afford confirmation of Sampson's views regarding the etiology of "perforating haemorrhagic" or "chordate" cysts of the ovary. These, together with the secondary cysts in the pelvis which are produced after their rupture, he regards as due to the activity of menstruating endometrial tissue in the ovary. Cornual endometrium, transplanted into the pelvic cavity, mesosalpingeal fat, or ovary, were found after seventy days to have grown where placed or in the neighbourhood; to the naked eye and microscopically the ectopic growth resembled multilocular cyst adenomata of the human ovary. The implantation cysts never attached themselves to the abdominal wall or mesentery, and only in one instance to the omentum. Sampson found that implanted human tumours underwent retrogression after castration; Jacobson in a series of rabbits whose ovaries were removed at the time of pelvic transplantation of endometrial fragments found that the experimentally produced cyst was only one-fourth the size of that in the first series. In two animals killed in the oestral period haemorrhage had occurred in the cystic tumours resulting from endometrial transplantation.

## 485. Febrile Abortions.

From the statistics collected during the last twelve years of 24,000 febrile abortions G. WINTER (*Zentralbl. f. Gyn.*, September 22nd, 1923, p. 1489) brings to light some interesting facts. Mortality is greatest with streptococci (15.5 per cent.), the haemolytic variety giving a mortality of 20.8 per cent. and the non-haemolytic of 11.1 per cent. Next in virulence come staphylococci (8 per cent.), *B. coli* (7.3 per cent.), and "saprophytes" (3.1 per cent.). The author distinguishes between two types of febrile abortions—the parovular, in which the decidua, cervix, or vagina is primarily infected, and the ovular, in which the ovum is the seat of primary infection. He also distinguishes between the uncomplicated type, where infection is confined to the uterus, and the complicated, where extension has occurred into the parametrium, etc. The mortality in uncomplicated cases is 2.7 per cent., independent of treatment and nature of bacteria, whereas in complicated cases it is 47.5 per cent., this mortality being derived from diffuse peritonitis, pyaemia, and septicaemia. The author comes to the conclusion that early evacuation of the ovum is the best method of treatment, for in the ovular type the source of the trouble is got rid of, whereas, in the parovular, involution follows evacuation and the chance of infection spreading is minimized by the closing of the lymph spaces and the decreased circulation. Spontaneous evacuation is deemed to be the best method, and this was effected in 72 per cent. of cases by the use of oral, intramuscular, and intravenous quinine. The mortality in such cases was only 1 per cent. With the expectant method of treatment, which is often warranted in the streptococcal cases, as the cocci frequently disappear owing to extensive growth of saprophytes, the mortality is slightly greater, being 1.1 per cent., whereas with active manual treatment the mortality rises to 2.9 per cent., the danger being most pronounced in complicated abortions. Active treatment with a blunt curette is ardently recommended by some, and Schottmüller cured in this way 33 cases infected by haemolytic streptococci. The advantages claimed for it over manual removal are that the uterus is not squeezed and pressed by the external hand, but is allowed to remain quiet, and also any extrauterine infections are not interfered with; whereas by manual removal the external hand may break down freshly made adhesions, perforate adnexal tumours, allow thrombi to loosen, etc., and drive the bacteria further into the lymph spaces.

## Pathology.

## 486. The Pathology of Periarthritis Nodosa.

G. MARINESCO, D. PAULIAN, and S. DRAGANESCU (*C. R. Soc. de Biologie*, November 3rd, 1923, p. 903) report a case of that very rare disease, periarthritis nodosa. The patient, a man of 28, neither alcoholic nor syphilitic but with a history of gonorrhoea, was admitted to hospital suffering from severe sensory and motor disturbances, muscular swellings, painful articulations, enlarged spleen, and oedema of the lower extremities. He died three months after the first manifestation of symptoms. Extensive histological examinations were carried out by the authors. The lesions affected the small and medium-sized vessels, both arteries and veins, but left the larger vessels and the capillaries intact. Three stages could be determined in the evolution of the disease. In the first there is an infiltration of the adventitial coat with polymorphonuclear cells, with lymphocytes, and with occasional plasma cells; the endothelium is swollen, but the media is generally unaltered. In the second stage the intima is the seat of an intense proliferation leading to the obliteration of the lumen of the vessel. Numerous fibroblasts invade the wall, thrombi occur in the vasa vasorum, and the whole vessel becomes deformed, sometimes showing aneurysmal dilatations. In the third stage the existing thrombi become organized, and extensive cicatrization takes place. The middle and inner coats become fused into a single layer, which consists of granulation tissue. The small vessels of the liver, spleen, kidneys, heart, peripheral nerves, and the pneumogastries were extensively involved, but the central nervous system itself appeared to be unaffected.

## 487. The Viability of the Gonococcus Outside the Human Body.

THE outbreak of an epidemic of gonorrhoea amongst the girls in a children's sunbath in Düsseldorf led P. ENGERING (*Zeit. f. Hyg. und Infektionskrankh.*, September, 1923, p. 314) to investigate the capability of the gonococcus to live in the outside world. The technique employed did not reproduce natural conditions faithfully, but it may probably be trusted to give an approximate idea of the possibilities of the case. He found that in all cases the resistance of the organisms varied with the particular strain employed; some were definitely more susceptible to disadvantageous conditions than others, and as he only studied eight strains it is clear that his results register neither the maximum nor the minimum degrees which would be found as a result of the examination of a larger series. In sterile tap-water kept at a temperature of 22°C. gonococci lived from 3 to 10 hours; in the surface water of a swimming bath from 7½ to 10 hours; and in the deep water from the same bath from 8 to 14 hours. On pieces of linen infected with gonorrhoeal pus the organisms remained alive up to 4 hours if the linen were kept moist, whereas they died off in half an hour to an hour if it were allowed to dry. On wet sponges infected with a pure culture the cocci remained alive up to 24 hours. It is seen from these experiments that the viability of the gonococcus outside the human body is greater than it has generally been considered to be; knowing the extreme receptivity of the tissues of the body at certain ages to infection, one is forced to agree that in the interests of children it is of the greatest importance to take every hygienic precaution that is possible in practice.

## Renal Tumours.

## 488.

G. CARISI (*Il Policlinico, Sez. Chir.*, August 15th, 1923, p. 411), who records 8 cases, states that renal tumours are a rare affection. According to recent statistics compiled by Küster, they constitute only 0.6 per cent. of all renal diseases. Brodeur estimates their frequency at 1 per cent., and Abbé at 0.9 per cent. During the last twenty-five years only 50 cases have been seen in the surgical department of the Civil Hospital at Venice, where Carisi is an assistant. The following classification of renal tumours may be employed: (1) Tumours derived from the renal epithelium of an innocent, malignant, or mixed character—namely, adenoma, carcinoma, and adeno-carcinoma—and tumours derived from connective tissue elements, including innocent forms, such as fibroma, angioma, and lipoma, and malignant forms such as sarcoma. (2) Hypernephroma. (3) Tumours derived from rests and embryonic tissue, as well as the exception of a child tissue tumours of infancy. With the exception of a child aged 3 years, all Carisi's patients were adults aged from 20 to 74. Three were examples of the first group, three of the second, and two of the third. Nephrectomy was performed in each case, and all recovered except the patient aged 74, who died of diffuse bronchopneumonia six days after the operation.

THE STUDY OF NATURE AS SHEDDING LIGHT  
ON THE STRUCTURE AND FUNCTIONS  
OF MAN.  
TO THE ANTER OF THE DEEP AND ITS RELATION  
TO THE GROWTH OF MAN.  
DELIVERED AT THE SIXTH MEETING OF THE INTERNATIONAL  
SOCIETY OF SURGERY.

SIR WILLIAM MACEWEN, M.D., F.R.S.,  
FELLOW OF THE SOCIETY AND OF THE BRITISH MEDICAL  
ASSOCIATION.

IN the name of the British Section of the International Society of Surgery and its local committee it is my privilege to extend to our international colleagues a very hearty and hospitable welcome. We are not unmindful of the courtesy, kindness, and hospitality which the British members have invariably been received in the countries where the Congress has already met—three times in Belgium, once in the United States of America, and once in France. It will be the endeavour of the British Section to make our colleagues from beyond the seas feel "at home" in our midst, on this first meeting of the International Surgical Society in Britain.

One of the tragedies of the war was the disruption of intellectual co-operation between the contending peoples. The work done in one country is often complementary to that done in others, and the collaboration of the scientific workers of all nations forms a powerful stimulus to the spread of enlightenment throughout the world. It is for the general good that endeavour be made to reconstitute and sustain the intellectual life of Europe by international co-operation, especially in the ever-active and boundless realms of science.

In a recent address given by me the question was raised whether the medical profession did not concentrate their studies too much on human phenomena to the exclusion of the so-called divisions of Nature. The purely arbitrary conveniences, having no existence except in our own minds, for, after all, we are but a bit of Nature, and everything pertaining thereto must have a bearing on humanity. Investigation into comparative anatomy and physiology tends to illuminate the obscure problems of growth of structure and function in man, and as an illustration of this in one small field, attention is directed to some of the phenomena attending the growth and shedding of the antler of the deer, especially in its histological aspects, and the bearing which these have upon the growth of bone in man and other mammals. Three months, antlers of solid bone, which in some species grow to immense size. They carry these antlers for a few months, then shed them, and repeat the process every season. The antlers are branched outgrowths from the frontal bones of the skull, and are amongst the most remarkable and interesting instances of sexual dimorphism. The yearly recurrence takes place chiefly from June to August. Not only does the bone grow within these few months, but the whole antler is enveloped from base to tip by the velvet, which keeps pace with the rapid growth.

*The Velvet: its Function.*  
There is very little insulation between the vessels of the velvet and those of the bone in the antler. Besides supplying through its blood vessels heat and moisture and giving general protection as a cuticular covering and limiting membrane, the highly sensitive velvet serves at least two purposes, one to the antler itself and one to the animal as a whole. It protects the soft pulpy growing antler by causing the animal to eschew issues of combat and violent or even slight contact with foreign bodies. In

this way wounds of the antler with their attendant haemorrhage and risk of septic or pyogenic infection are prevented. Were it not so protected the pulpy antler might be burst, ruptured, or torn, and, being highly vascular, so much blood might be lost as to endanger the life of the animal. When the osseous matter in the antler has solidified there is no further need for this covering, which has already served its purpose. The growth of the bone at the corium compresses the blood vessels of the velvet and cuts off their blood supply, when the whole velvet withers, becomes dry and shrivelled, is cast off in ribbons or is stripped like a discarded glove. The solid antler now remains—a formidable, insensitive weapon.

*What is the Cause of the Annual Shedding of the Antler?*  
As one of the secondary sexual characters, the antler is usually described as merely an ornamental weapon. It is, however, more intimately correlated to the sexual function. Though the reproductive organs with their interstitial tissue are the *fontes of origo* of the antlers, the antlers, through the velvet, have a periodic reflex influence on the function of the testes. The phase of evolution and greatest sensitivity of the velvet corresponds to the period of minimal testicular activity as if a reflex inhibitive influence was exercised on the testes through the nerves of the velvet. When the antler has become well formed and sclerosed, the nerves and blood vessels are obliterated, and the velvet is shed. At this period the bloodless, nerves, insensitive structure is left as a weapon fit for combat. If, however, the velvet is to serve the retarding function over the reproductive organs, then it must be shed annually and grow afresh. The sensitivity of the antler at that early stage is thus probably purposive and is one reason for the antler being deciduous.

*Two Points regarding the Structure of the Velvet:*  
(1) The stratum lucidum—has it an independent vitality?  
(2) The cutis of the velvet grows directly on the bone.  
With regard to the structure of the velvet, with its composite cutaneous investment containing glands, hair follicles and appendages which are evolved with the rapidity and completeness of an embryonic structure, there are two points worthy of note from their bearing on surgical pathology. First, the stratum lucidum is more advanced in development during the growing period than the stratum Malpighii, the former appearing mature when the latter is still embryonic; osseous tissue is first rapidly covered by stratum lucidum, the stratum Malpighii following. This corresponds with what is found in wounds, where the stratum lucidum penetrates blood clot and advances almost *part partu* with the leucocytes, ahead of the stratum Malpighii, or on granulation surfaces where the stratum lucidum precedes the Malpighii, forming the "dry, red line" seen at the margin of a healing ulcer.  
May not the question be raised whether the current view be correct—that all the layers of the skin grow from the stratum Malpighii upwards, and that the superficial layers, more or less ecto? Would ecto cells be the first to regenerate?

The evidence adduced tends to indicate that the stratum lucidum possesses an independent vitality and is endowed with the power of more rapid surface extension than the deeper layer. This also obtains when the stratum lucidum is detached from the body and is grafted on to a granulation surface. It is of importance to have this layer of stratum lucidum, thin as it is, covering a wound, as it forms a barrier to the ingress of germs, and, once formed, the proliferation of the slower stratum Malpighii and the organization of the tissues inside the wound proceed apace. The deep cutaneous layers, however, provide a thicker covering for the wound and protect the interior from friction and injury.  
The second point is that in the antler one sees the cutis

**A VALUABLE FOOD BISCUIT**  
**MACFARLANE LANG & CO.'S**  
**DINNER TOAST**

The DINNER TOAST biscuit, the latest addition to our series of Food Biscuits, is composed of the finest wheaten flour, pure butter, malt and milk, contains but a trifling percentage of moisture, and makes a crisp, crusty appeal to the palate.

Primarily it has been introduced for persons of dyspeptic tendencies who cannot partake of ordinary bread or toast with comfort. For such, the DINNER TOAST BISCUIT, both from the standpoint of EASE OF DIGESTION AND HIGH CALORIC VALUE, provides an excellent substitute.

Taken also with a glass of milk, a cup of beef-tea or other nutritive fluid, the DINNER TOAST biscuit makes a sustaining emergency meal.

## The latest Authority

to give emphatic pronouncement on the qualities of the AcoustiCON is "THE PRACTITIONER,"  
that in the October 1923 issue said:—

"The Acousticon . . . is a highly efficient apparatus which can be seriously recommended as an Aid to Hearing. Our tests were not only of the efficiency of the Instruments, but also of their manufacture. We have no hesitation in saying that both are of the highest order, and accordingly we recommend those Members of the Profession who have Patients to whom the use of such Instruments is necessary, to give the Acousticon a good trial."

The AcoustiCON has prospered since 1899 largely because of the strong support it has received from the Medical Profession. It is to-day used exclusively in the Royal Free and London Hospitals for conversing with deaf patients. . . . The

is supported by such a weight of opinion among Aural Specialists and—naturally—the general public who use it that it is literally the standard apparatus of its kind. If you are unacquainted with it, please let us demonstrate it to you and tell you of the Aural Specialists who recommend it.

they may be also very irregular, and even ragged in outline, in this respect differing greatly from those of the cortex, which are sharply defined and compact. Many of the cells, however, show brown granules in many of the medullary cells, and most workers are of opinion that these chromatin granules are limited to the medulla, though Cranner<sup>1</sup> shows very convincingly that they are also to be found in the zona recticularis. We have also noted this in cases, and apparently in greater abundance in the medulla; at any rate, this applies to the human subject, according to our experience. The cytoplasm of the cells stains well with eosin, and there is but little vacuolation, with the oil-immersion lens numbers of the eosin-stained granules can be seen—7 mitochondria. The nucleus is small in comparison to the cell; it is round, stains deeply, and contains numerous chromatin granules, some intensely black and coarse when stained by Del Rio Herrera method, and others of dust-like fineness; a distinct nucleolus are for the most part of uniform size and shape. In normal glands there are very few nuclei without surrounding cytoplasm, and those are paler and contain fewer granules than the nuclei contained in the cells. Moreover, instead of being round, they are generally oval or fusiform in shape. Mitosis has been observed in the cells of the medulla of many glands and also in the zona recticularis. Cranner<sup>1</sup> has found mitosis in the medulla, but much less frequently than in the cortex. In many cases groups of sympathetic ganglion cells were found in the medulla or just between the cortex and medulla, and occasionally bundles of non-medullated fibres. Cortex and medulla react as a whole in a different way to stains, for whereas the medulla takes up the basic, the cortex takes the acid stain.

Size and Weight of Adrenal Glands in One Hundred Cases.

Size.—The adrenals are glands so small and light that slight differences in their size and weight may have a certain significance. These differences may sometimes be marked by still more clearly observed upon studying a stained section through the gland in its thickest part. It can be noted, on the one hand, without the aid of the microscope that the adrenal glands of a case of dementia praecox are, as a general rule, smaller than in cases belonging to any other class, and, on the other hand, the adrenal glands of a case of general paralysis are usually larger. It was also noted that a section of the gland in a case of tuberculosis did not differ, as a general rule, from that of the section of the gland of a normal hospital case dying of injury.

Weight.—The average weight for each group of cases was taken. Many of the glands in dementia praecox only weighed from 2.8 to 4 grams; the average weight, however, in this class was higher than might have been expected. Several factors contributed to the raising of this average, of which the following were the principal.

One case with heavy adrenals had been clinically diagnosed as dementia praecox and is included in the list, but its history showed that it was doubtful whether it was a case of dementia praecox. Four were pure adrenal cases, which would probably account for some increase of the weight owing to the enlargement of the cortex, connected with the puerperal condition.

A few adrenals were heavier than normal, owing to the great fibrosis of their medulla.

The average weight of adrenals in dementia praecox cases = 6.326 grams (women = 6.518 grams, men = 5.327 grams).

Average weights were as follows:

| Class             | Weight (grams) |
|-------------------|----------------|
| Dementia praecox  | 6.326          |
| Other psychoses   | 6.60           |
| General paralysis | 7.35           |
| Tuberculous cases | 6.28           |
| Hospital cases    | 7.21           |

The weights in the different classes are probably more clearly shown in the following table. The sum of the right and left adrenal is taken in each case, and the percentage of cases between certain weights is given:

| Dementia praecox (21 cases) |          | General paralysis of the insane (21 cases) |          | Various psychoses (8 cases) |          | Tuberculosis (10 cases) |          | Hospital cases (22) |          |
|-----------------------------|----------|--------------------------------------------|----------|-----------------------------|----------|-------------------------|----------|---------------------|----------|
| Grams.                      | Percent. | Grams.                                     | Percent. | Grams.                      | Percent. | Grams.                  | Percent. | Grams.              | Percent. |
| 5 to 10                     | 10.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |
| 10 to 15                    | 15.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |
| 15 to 20                    | 20.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |
| 20 to 25                    | 25.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |

| 75 to 80                    | 80.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |
| 80 to 85                    | 85.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |
| 85 to 90                    | 90.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |
| 90 to 95                    | 95.1     | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |
| 95 to 100                   | 100.1    | 43                                         | 23       | 43                          | 5        | 43                      | 5        | 37                  | 5        |

Note the high percentage of dementia praecox cases between 5 and 10 grams, and of cases of general paralysis of the insane between 15 and 25 grams.

The average for the normal gland of this series is 7.21 grams—a much higher average than Elliot's, which was between 4 and 5 grams. "Cranner" gives 6 to 7 grams as the average weight, and 7.5 grams as his average.

Ratio of the Area of Cortex to that of the Medulla.

So striking were the differences in the width of the medulla in the different cases that it was thought advisable to find means of arriving at some idea of the relative areas of the cortex and medulla. This was at first done by actual comparative microscopic measurements through the thickest portion of the medulla, but it was felt that this method was open to many fallacies, so the following method was adopted. It has been previously explained how the glands were cut and stained. The magnified outline of the section was drawn on paper of equal thickness by means of an Linderger projection apparatus. The medulla was also outlined, and this is a very simple matter, for, owing to the fact that their staining reactions are so different, the cortex and medulla stand out quite clearly from each other. The medulla and cortex having been delineated upon the paper were then separately cut out and each accurately weighed; thus a representation of the area in terms of weight was obtained. It was found that the normal glands showed an average ratio of 2.7—that is, the cortex covered 2.7 times as much area as the medulla. Tuberculosis cases showed an average ratio of 3.7, and general paralytics one of 3.2. The average for the dementia praecox cases was, however, a much higher one, and showed that the cortex covered 8.6 times more area than that of the medulla. If this fact be coupled with the fact that the average dementia praecox adrenal is relatively a smaller organ, it is probable that the deficiency in weight in most of the cases was, in great measure, due to deficiency in a medulla. In fact, in some of these cases the medulla is a mere narrow strip of tissue; in a few cases, however, the medulla is as extensive as in normal cases because of great substitutive fibrous hyperplasia. The cases investigated by Dr. Dawson (referred to in the earlier part of this communication) have for the most part not died, therefore we have no precise data regarding the correlation of blood pressure, Goetsch reaction, acrocyanosis, katonias, and anergic stupor with the degree of atrophic change in the medulla of the adrenal gland.

I am at present instituting an intensive research on the relation of the histological changes in the reproductive organs, the whole endocrine system, and the vegetative nervous system, to carefully recorded clinical investigations, including basic metabolism in individual selected cases of dementia praecox. (F. W. J.)

There does not seem to be any literature in which accurate figures can be found to compare with those of this series; Elliot and "Cranner," however, have worked out this ratio in animals, and from the figures obtained have deduced the proportions of cortex and medulla in man. The proportion of cortex to medulla which they give is somewhat higher than that which we have found in this series. A graph shows well the ratio of the cortex to the medulla in the different classes of case.

(u) Lipoid.—It was found that in most of the cases of dementia praecox, in all cases of general paralysis and the other psychoses, as in the normal cases, it was apparent to

form is due to the less marked and less noisy character of the danger symptoms, and given constant observation and readiness of resource, these need not be more feared than those of ether? I am sure that in many cases chloroform has been blamed as against ether where the latter was either inadmissible or inadvisable.—I am, etc.,

London, S.W., July 7th.

#### FREEDOM OF NEGRO RACES FROM CANCER.

SIR,—The letter of Dr. Fouché will interest all medical men practising in West Africa, who can, I am sure, amply confirm his remarks with regard to the rarity of cancer in pure negroes.

It is true it occasionally occurs in towns on the seaboard, such as Accra, Lagos, and Calabar, which have a heterogeneous population and where the natives have lived in close contact with Europeans for upwards of four hundred years, but even then it is a rare condition, differing in this respect from sarcoma. Appendicitis is likewise uncommon except in the coast towns, and the only case I have seen alive or in the *post-mortem* room (apart from a case in a half-caste that occurred at Accra in 1913) was secondary to a filarial infection of the psoas muscle.

In Northern Nigeria the extreme rarity of carcinoma may be judged by the fact that the only recorded case, at any rate in recent years, was one of carcinoma mammae in an old woman from Sokoto, and this specimen is now in the Museum of the Royal College of Surgeons. In Northern Nigeria, moreover, the women do not commonly cover their breasts, and it is therefore more than usually easy to observe cases of this kind among the 9,000,000 inhabitants.

I may add that during a period of two years in Abyssinia I neither saw nor heard of a case of carcinoma from my French, Greek, Italian, and Russian colleagues, all of whom had large practices in the capital. The Abyssinian, moreover, is not a negro, though intermarriage with slave tribes has produced negroid features in many cases.—I am, etc.,

London, S.W., July 2nd.

West African Medical Service.

#### A HOSPITAL CONTRIBUTORY SCHEME.

SIR,—Much correspondence recently appeared in your columns concerning hospital policy, the tenor of which fairly reflected the absence of precedent to guide or constructive policy to build on. It may therefore be of interest to your readers to learn how we in Sevenoaks have tried to solve our problems.

Last year a cottage hospital of a dozen beds was rebuilt into the Sevenoaks and Holmesdale Hospital with twenty-six beds; it contains two main wards, private wards, operating theatre, x-ray rooms, laboratory, etc.

In order to find support for a larger hospital, we started a contributory scheme, under which a worker pays 2d. a week for himself and family, except such children as are themselves wage-earners, the latter also contributing 2d. a week. The income limit of those who join was fixed at £200 a year. In conformity with the British Medical Association policy, the medical staff claimed and obtained a "token" payment out of the premiums of 1 per cent. After less than a year the number of members who are paying weekly is approaching 2,000, and we find that the total of their premiums is very little short of the whole cost to the hospital of those contributors admitted during the same period.

Recently application was made to the Hospital Committee by workers earning from £200 to £375 a year to be enrolled under the scheme. The matter was very thoroughly considered by the medical staff, with the result that they unanimously decided that they would be ready to attend persons enjoying such incomes, under a contributory scheme, provided that the following fees were paid:

- (1) For every case admitted £3 3s. to the doctor attending.
- (2) An annual fee of £5 5s. for every major operation.
- (3) A fee of £1 1s. for out-patient operations.

The honorary treasurer and honorary secretary estimated bed-days per 100 members and prepared figures, and found that premiums scaled from 15s. to 30s. per annum according

to income would meet, with a margin, the total cost to the hospital of maintenance together with the above professional fees. The Committee has therefore given its consent to this extension of the contributory scheme.

As a hospital we may then, I think, claim that we have worked out a satisfactory plan for contract attendance of all below the paying-ward class, with due consideration of professional interests. And this has been due, first of all, to the ideal state of good feeling and united action obtaining amongst all the medical men in Sevenoaks, with the consequent thorough discussion of everything which touches their interests; secondly, to the fact that all doctors in the district are allowed to attend their own cases; thirdly, to the consideration of an able lay committee, the members of which have successfully attacked and mastered the new situation which hospitals have to face; and, lastly, perhaps not a little to the presence of a member of the medical staff on the Committee, acting as honorary secretary, and therefore in a position to act, as it were, as liaison officer between Committee and medical staff.—I am, etc.,

F. MARSDEN BURNETT, M.D., D.P.H.,  
Hon. Secretary, Sevenoaks and Holmesdale Hospital.

Sevenoaks, July 3rd.

#### HYDROLOGY.
